A truck accident can result in only minor property damage (fender bender) or major property damage, an injury to the truck driver or a member of the public, or a fatality. Saricks and Kvitek (1994) give state-by-state truck accident, fatality, and injury rates. The values used in the primary study area, in conjunction with the accident rates given in subsections F.4.2.2 and F.4.2.3, are 0.21 for the conditional probability of an injury in a truck accident, and 0.01 for the conditional probability of a fatality in a truck accident (DOT 1995a). To evaluate this risk, the appropriate truck accident rate (subsection F.4.2) is multiplied by the number of truck miles (subsection F.4.3).

F.3.4 Cargo-Related Risk Measures

The cargo-related health effects are a result of the intrinsic nature of the cargo; i.e., radioactive material and HAZMAT. HAZMAT presents no health risk unless the material is released in an accident. RAM can present a health risk caused by release in an accident as well as by the normally occurring (incident-free) low-level radiation field external to the packaging. The latter is referred to as incident-free risk.

F.3.4.1 *Incident-Free Risk Measure (Radioactive Materials Only)*

The doses to three groups of the public, truck and air crew members, and to the maximally exposed individual (MEI) are quantified separately for the SWEIS. Each of the dose calculations is based on parameters such as the number of shipments and the radiation level of the shipments. Either the RADTRAN or the ADROIT computer codes described in subsection F.4.4 is used to perform the calculations. The collective doses are expressed in person-rem, and the MEI dose is expressed in rem; the conversion from person-rem and rem to human health effects is described in subsection F.4.4.5. The dose calculations are described in the following subsections.

People Along the Truck Route

The dose each person would receive depends on his or her distance from the highway and the speed of the truck as it passed. The already low radiation level at the truck would drop off rapidly as distance from the truck increased. Also, the faster the truck passed, the less time there would be for people to be exposed. The collective doses are calculated for all people living or working within 0.5 mile (0.8 kilometer) on each side of the highway for each route considered.

People Sharing the Truck Route

People in vehicles traveling in the same or the opposite direction as the shipment, as well as people in vehicles passing the shipment, would have the potential for close exposure to the radiation level from the truck. The collective doses are calculated by considering traffic count and vehicle speeds for rural, suburban, and urban areas for each route considered.

People at Truck Stops

Typical truck shipments involve stops for meals, fuel, and rest or driver change. During these stops, the public in the vicinity of the truck would be exposed to a stationary source of radiation. A simple, conservative model is used to calculate the collective doses for each route considered.

Crew Members

Collective doses are calculated for truck and aircraft crew members as well as for handlers transferring the shipment from a truck to an aircraft and vice versa for each route considered. No air shipments from or to LANL use passenger aircraft.

Maximally Exposed Individual

A hypothetical MEI is assumed to live 98 feet (30 meters) from the highway, and all trucks are assumed to pass the MEI at a speed of approximately 15 miles per hour (24 kilometers per hour).

F.3.4.2 *Releases from Accidents*

Given a very severe transportation accident, packaging/containers for radioactive/HAZMAT could fail and release their contents. Except for some shipments with very high radiation levels, such as irradiated targets for production of medical isotopes, subsequent dispersion of the material into the atmosphere would be required to produce a significant exposure to members of the public. Either the RADTRAN or ADROIT computer code described in subsection F.4.4 is used to perform the calculations for RAM. The potential acute dose for an individual is expressed in rem, and the potential latent dose for collective population exposure is expressed in person-rem.

The effects of dispersing toxic materials are expressed as the number of persons who could be exposed to life-threatening or injury-producing concentrations. Detonation effects are expressed as the number of persons who could be killed as a result of a fireball or the number of severe burns that could result.

F.4 TRANSPORTATION RISK METHODOLOGY

F.4.1 Introduction and Overview

The analyses of both radioactive and HAZMAT risks are largely accomplished with standard computer codes; the computer code methodology is documented in more detail elsewhere and will not be repeated here. However, the standard parameters (also called the default values) used in the RADTRAN (Neuhauser and Kanipe 1995) code are presented in this section to ensure the repeatability of the results.

The first key parameter, truck and aircraft accident rates, is discussed in subsection F.4.2. State of New Mexico data are used to determine accident rates from the LANL site to I–25, and a standard state-by-state compilation is used for accident rates elsewhere. On-site truck accident rates and accident rates specific to the SST are presented. Aircraft accident rates are also described.

The second key parameter, truck mileage, is evaluated by using the HIGHWAY code (Johnson et al. 1993) as described in subsection F.4.3. The HIGHWAY code also produces population density values (a key parameter) based on 1990 census data as discussed in subsection F.4.3. State-by-state mileages are quantified by HIGHWAY in each of three population density categories: rural, suburban, and urban. The route between I–25 and Pojoaque and between Pojoaque and LANL is also subdivided by these population density categories.

The RADTRAN or ADROIT codes are used for incident-free dose calculations and for doses from accidents with RAM. An overview of the incident-free methodology and the specific input parameters is presented in subsection F.4.4, as is the accident calculation methodology. Event trees are used for defining HAZMAT and on-site RAM accident scenarios and determining their frequency. The ALOHA™ (NSC 1995) and DEGADIS (Havens and Spicer 1985) codes are used for chlorine accident dispersion calculations.

F.4.2 Accident Rates

Four sets of truck accident rates are used in the analysis: state-specific; route-specific, between I–25 and the LANL site; on-site roads with and without road closure; and the SST.

F.4.2.1 *State-Specific Truck Accident Rates*

Truck accident data for the years 1986, 1987, and 1988, from DOT Office of Motor Carriers, were divided by estimated truck miles data for the same years from DOT Federal Highway Administration (Saricks and Kvitek 1994). The average accident involvement rates for the U.S. and for the State of New Mexico are given in Table F.4.2.1–1. (Note that U.S. 285 to WIPP facility is a federal-aid primary highway.) Saricks and Kvitek point out that the New Mexico urban interstate computed value is more than two standard deviations greater than the national average and indicates decimal place errors in the New Mexico truck mileage data.

F.4.2.2 *Regional Truck Accident Rates*

Truck accident data for U.S. 84/285, NM 502, NM 4, and East Jemez Road were obtained from

TABLE F.4.2.1–1.—*Average Truck Accident Rates*

HIGHWAY TYPE	ACCIDENT RATE			
	ACCIDENTS PER KILOMETER		ACCIDENTS PER MILE	
	U.S.	NM	U.S.	NM
Urban Interstate	3.58×10^{-7}	9.64×10^{-7}	5.76×10^{-7}	1.55×10^{-6}
Rural Interstate	2.03×10^{-7}	1.92×10^{-7}	3.27×10^{-7}	3.09×10^{-7}
Federal-Aid Primary	3.94×10^{-7}	4.77×10^{-7}	6.34×10^{-7}	7.68×10^{-7}

Source: Saricks and Kvitek 1994.

the State of New Mexico (Fenner 1995 and Fenner 1996) for calendar years 1990 through 1994. Truck mileage data were obtained from the State of New Mexico (Vigil 1996) for the calendar years 1992 through 1994. The traffic count for East Jemez Road is assumed to be 65 percent of that on NM 4 on the basis of a different set of traffic counts (BAA 1993). The data and the computed accident rates are given in Table F.4.2.2–1.

Because no accidents occurred on NM 4, the East Jemez Road rate is used for conservatism. The truck accident rates in Table F.4.2.2–1 for primary highways are lower in low population areas and higher in high population areas than the corresponding values in Table F.4.2.1–1 for federal-aid primary highways in New Mexico. This difference is expected because the rate in Table F.4.2.1–1 is an average of rural, suburban, and urban areas.

F.4.2.3 *On-Site Truck Accident Rate*

In previous on-site transportation risk analyses at LANL, values from Harwood and Russell (1990) have been used for accident frequency. These values are the most widely used values for truck transport analysis. Their value for two-lane rural roads, 2.19 x 10^{-6} accidents per mile (1.36 x 10^{-6} accidents per kilometer) was considered representative for non-rush-hour traffic on the LANL site (Rhyne 1994b). (An urban rate of 8.66 x 10^{-6} accidents per mile would be appropriate for Diamond Drive and vicinity.) The representative value used here is a factor of two higher than values for NM 4 and East Jemez Road, but will be conservatively used in the SWEIS for on-site risk analyses. This analysis will also be consistent with the earlier risk analyses that are being incorporated into the SWEIS.

The rates in Tables F.4.2.1–1 and F.4.2.2–1 are averages for trucks traveling in all types of weather, day and night. However, trucking firms that strongly emphasize safety can achieve a factor of 10 reduction in accident rate (Anonymous 1994, Anonymous 1990, Wilson 1990, and OTA 1988). The emphasis on driver safety training and the vehicle maintenance program for RAM shipments on the LANL site are comparable to the safety programs at commercial trucking firms that produced a factor of 10 reduction in accident rate. RAM shipments are made only during daylight, non-rush-hour traffic, and good weather. Drivers work a regular schedule and 8-hour days. These precautions and possibly others lead to an accident rate reduction factor of at least ten for on-site shipments at LANL. As a result, the truck accident rate used in this appendix for on-site transport of RAM and HAZMAT, using DOE trucks and LANL drivers, is 2.19 x 10^{-7} accidents per mile (1.36 x 10^{-7} accidents per kilometer). The factor of 10 could also be applied to many off-site shipments. However, because it cannot be applied uniformly, it is conservatively not applied to any off-site shipments.

TABLE F.4.2.2–1.—*Truck Accident Rates in the Santa Fe to Los Alamos Area (1990 Through 1994)*

ROUTE	MILE MARKER RANGE	TOTAL NUMBER OF ACCIDENTS	AVERAGE TRUCK TRAFFIC (VEHICLES PER DAY)	TRUCK ACCIDENT RATE	
				ACCIDENTS PER KILOMETER	ACCIDENTS PER MILE
Route Through Santa Fe	160.7 to 167.6[a]	97[b]	2,104[c]	2.27×10^{-6}	3.66×10^{-6}
U.S. 84/285	167.6 to 180.2[a]	17[b]	1,677[c]	2.74×10^{-7}	4.41×10^{-7}
NM 502	18.5 to 6.3[a]	5[b]	462[c]	3.02×10^{-7}	4.86×10^{-7}
NM 4	67.8 to 66.5[a]	0[a]	520[d]	6.71×10^{-7}	1.08×10^{-6} [a]
East Jemez Road	NA (distance is 6 miles)	4[a]	520[c]	6.71×10^{-7}	1.08×10^{-6}

[d] See text
NA = Not applicable

In conformance with DOT regulations (60 FR [188] 50297), some on-site shipments are made by temporarily closing the affected portions of public roads through the LANL site. Under these conditions, many of the truck accident types can be reduced significantly or even eliminated. According to an analysis of the types of truck accidents and the LANL site administrative controls (Rhyne 1994b), the truck accident rate for closed roads is 1.44 x 10^{-8} accidents per mile (8.95 x 10^{-9} accidents per kilometer). This procedure has been used and defended previously (Rhyne 1985) and has compared well with data (Green et al. 1996). The on-site truck accident rates are given in Table F.4.2.3–1.

F.4.2.4 *Safe Secure Tractor Trailer Accident Rate*

The SST accident record is excellent. In the 9-year period between 1988 and 1996, the overall accident rate was 7.7 x 10^{-8} accidents per mile. The number of SST accidents is too small to support allocating this overall rate among the various types of routes used in the accident analyses (urban interstate, rural interstate, other urban, and other rural). Therefore, data for the relative rates of accidents on these route types for five-axle vans in the appropriate weight range (Phillips et al. 1994) was used to allocate SST rates among these route types. The resulting SST rate for each

TABLE F.4.2.3–1.—*Truck Accident Rates at the LANL Site*

TRANSPORT DESCRIPTION	ACCIDENT RATE	
	ACCIDENTS PER KILOMETER	ACCIDENTS PER MILE
Off-Site Trucks at LANL Site[a]	1.36×10^{-6}	2.19×10^{-6}
DOE Trucks with LANL Drivers[b]	1.36×10^{-7}	2.19×10^{-7}
Trucks with Road Closure[b]	8.95×10^{-9}	1.44×10^{-8}

route type is presented in Table F.4.2.4–1. The "other rural" value in Table F.4.2.4–1 corresponds to the "DOE trucks with LANL drivers" value in Table F.4.2.3–1. The first two values of Table F.4.2.4–1 can be compared with the first two values of Table F.4.2.1–1 to see the effect of the strong safety culture described in subsection F.4.2.3.

F.4.2.5 *Aircraft Accident Rate*

Air transport to and from LANL is assumed to be by commercial air-cargo carriers such as Federal Express to and from the Albuquerque International Airport (transport between this airport and LANL is by truck or van). Shipments are picked up in the carrier's van and taken to an airport, flown to the destination city, and taken to the final destination by the carrier's van. Commercial air-cargo carriers are categorized as large certified air carriers and are assumed to fall in the subcategory of "large nonscheduled service" for which the 1992 accident rate was 7.9 x 10^{-9} accidents per mile (DOT 1992). The accident rate has been at or below this value for 4 out of the 5 years between 1988 and 1992. The accident rate is about twice that for large, scheduled service.

Accidents involving air shipments were screened relative to truck shipments. The aircraft accident rate per mile is two orders of magnitude less than the truck accident rate per mile for similar shipments. The probability of a high severity accident is higher for aircraft, but not much higher (section F.4.4.3).

TABLE F.4.2.4–1.—*Safe Secure Trailer Accident Rates*

HIGHWAY TYPE	ACCIDENT RATE	
	ACCIDENTS PER KILOMETER	ACCIDENTS PER MILE
Urban Interstate	3.01×10^{-8}	4.85×10^{-8}
Rural Interstate	4.45×10^{-8}	7.16×10^{-8}
Other Urban	1.87×10^{-7}	3.01×10^{-7}
Other Rural	1.83×10^{-7}	2.95×10^{-7}

F.4.3 Route, Mileage, and Population Density Determination

The scope of the SWEIS calls for analysis of LANL shipments of RAM and HAZMAT to and from other DOE sites as well as to and from numerous educational or commercial sites. The calculation approach is to determine the RAM and HAZMAT shipments by alternative (section F.5). The routes between DOE sites are then determined for the shipments unique to those sites, and routes between geographical areas of the U.S. are determined for all other shipments. Five geographical areas are defined for RAM shipments: northeast, southeast, northwest, southwest, and New Mexico. The cities selected as representative of each area are Concord, Massachusetts; Aiken, South Carolina; Richland, Washington; Berkeley, California; and Albuquerque, New Mexico. The cities were chosen as conservatively representative on the basis of the number of shipments to various locations in the geographic area in the 1990 through 1994 baseline (see subsection F.5.2). In the northwest, southeast, and southwest, cities near DOE sites were chosen because they appeared to be reasonable choices for general shipments to and from the region. The routes for each shipment were then used to estimate shipment mileages (see Table F.6.1–1 for distances between LANL and the representative cities for RAM and HAZMAT shipments).

The representative truck routes were determined by using the routing code HIGHWAY, Version 3.3 (Johnson et al. 1993), available to the public and DOE users through the TRANSNET computer system at Sandia National Laboratories (SNL). The HIGHWAY code contains a database of at least 240,000 miles (386,000 kilometers) of roads.

The population densities along a route are derived from 1990 census data from the U.S. Bureau of the Census. Rural, suburban, and urban areas are characterized according to the following breakdown: rural population densities range from 0 to 139 persons per square mile (0 to 54 persons per square kilometer); the suburban range is 140 to 3,326 persons per square mile (55 to 1,284 persons per square kilometer); and urban areas encompass all population densities greater than 3,326 persons per square mile (1,284 persons per square kilometer).

All routes for shipment of radioactive or HAZMAT into or out of LANL are conservatively assumed to pass through Santa Fe for the baseline analysis (the comparative analysis of the proposed bypass route is discussed in section F.7 of this appendix). The route between the LANL site and I–25 in Santa Fe is subdivided into two segments. The corresponding HIGHWAY results are shown in Table F.4.3–1. Similar information was generated from I–25 in Santa Fe to each origin or destination on a state-by-state basis.

Cargo air shipments are also made to and from the LANL site. Air shipments arrive at the Albuquerque Airport and are transported by truck to the LANL site or vice versa. Air shipments are included in incident-free impact analyses, but screened from accident analyses, as discussed in section F.4.2.5.

F.4.4 RADTRAN and ADROIT Analyses for Radioactive Materials

Two of the four risk measures described in section F.3 are modeled by RADTRAN (Neuhauser and Kanipe 1995) (refer to Figure F.3–1). The RADTRAN code is designed to produce conservative estimates of the radiological dose to workers and the public during incident-free transportation and the radiological risks from potential accidents.

The RADTRAN code was originally developed in 1977 in conjunction with the preparation of NUREG–0170, *Final Environmental Statement on the Transportation of RAM by Air and Other Modes* (NRC 1977). Subsequent versions have expanded and refined the analytical capability of the code; the current version is RADTRAN 4 (Neuhauser and Kanipe 1995). RADTRAN is maintained, updated, and improved on a continuing basis by SNL for DOE. RADTRAN is available to the public as well as to DOE users through the TRANSNET computer system at SNL. RADTRAN is widely accepted and used both in the U.S. and internationally.

The ADROIT code was developed in the 1992 through 1994 time frame to replicate the RADTRAN incident-free and accident estimates specific to transport in an SST. The

TABLE F.4.3–1.—*Route Segment Information from I–25 to LANL*

ROUTE SEGMENT	TOTAL DISTANCE		AVERAGE POPULATION DENSITY (PERSONS/km^2)			DISTANCE BREAKDOWN (km)		
	km	MILES	RURAL	SUBURBAN	URBAN	RURAL	SUBURBAN	URBAN
I–25 Exit 282 to U.S. 285/84 Junction with NM 502	32.2	20.0	11	625	2,228	24.0	6.3	1.9
Junction of NM 502 and U.S. 285/84 to NM 4 and Junction of East Jemez Road and Diamond Drive	30.6	19.0	14	312	0	28.5	2.1	0.0

code was developed from first principles; and although the end results are very similar to RADTRAN, the specific models may vary. Significant differences include the use of an event tree rather than an accident severity matrix (subsection F.4.4.2). As used in this analysis, the codes can be considered equivalent.

F.4.4.1 *Incident-Free Risk Parameters*

The most important parameter for evaluation of incident-free risk is the package exterior radiation level. The transport index (TI) is used in RADTRAN to characterize the exterior radiation field. The TI is defined in 49 CFR 173.403(bb) as "the exposure rate in millirems per hour at a distance of 1 meter from the surface of the package," and DOT regulations limit the value of TI to 10 or less for general commerce shipments. The TIs for the LANL baseline shipments discussed in section F.5.0 are based on measurements. The average truck shipment TI is less than 2, and the average air shipment TI is approximately 0.1. During the data-gathering process for the SWEIS alternatives, LANL transportation specialists were asked to place a reasonable upper bound on the average for the entire shipment type being discussed. (An average is appropriate for incident-free risk in contrast to accident risk.) When there is little or no experience with a particular shipment type, the usual procedure is to use the legal limit as a conservative value.

The alternative-specific parameters are given in section F.5.0, and those generic to all alternatives are given in Table F.4.4.1–1. Two exceptions to Table F.4.4.1–1 are used: a value of 1.0 is used for the urban city street fraction in Santa Fe, and the fractions of rural and suburban travel on freeways are 0.347 between I–25 and Pojoaque and 0.525 between Pojoaque and LANL.

F.4.4.2 *Accident Severity Categories*

Accident forces include fire, crush, impact, and puncture, and many accidents involve a combination of thermal and mechanical forces. The severity of accidents is categorized in RADTRAN by up to 20 categories for the magnitudes of accident forces and the associated probabilities. The accident severity category approach seeks to relate the magnitude of an accident force with mode of package response (e.g., small structural strains produce no release; larger strains produce loss of containment function and gross rupture). Ideally, such an analysis is done for each type of package; however, as pointed out earlier, this level of detail is impractical for the SWEIS. Most DOE environmental impact statements (EISs) rely on the accident severity categorization scheme described in an NRC report commonly referred to as NUREG–0170 (NRC 1977). NRC divided the spectrum of accident severities into eight categories that are independent of a specific accident sequence. The eight categories are designed to take into account all credible accidents, including accidents with low probability but high consequence and those with high probability but low consequence. The probabilities that correspond to the accident forces characterizing a particular package response are based on analyses by Dennis et al. (1978) or Clarke et al. (1976) The NUREG–0170 accident severity categories and associated probabilities are given in Table F.4.4.2–1.

Category I accidents are the least severe and the most frequent. Category I is considered to include all those accidents less severe than the normal conditions of transport in which Type A packages are shown by tests to be capable of retaining all their contents (section F.2.0). Category II is considered to include accidents more severe than Category I but less severe than the accident conditions in which Type B packages are shown by tests to be capable of retaining all their contents. The percentage of

TABLE F.4.4.1–1.—*Parameter Values for Incident-Free Risk Quantification*

PARAMETER DESCRIPTION	TRACTOR-TRAILER	CARGO AIR	DELIVERY VAN
Speed in Rural Area, kilometers per hour	88.49	691.90	88.49

VIII	1.5×10^{-5}	0.9	0.05	0.05

Source: NRC 1977

truck accidents less severe than Type B test conditions is 91 percent according to the 1977 NRC report. A 1987 NRC study (LLNL 1987) estimated that 99.4 percent of the truck accidents would not cause a release from a Type B package. The more conservative results from the older NRC study are used in the SWEIS transportation risk analyses. Packages for plutonium are required to have both inner and outer containment vessels (10 CFR 71.63). Tests with these packages produced no structural damage to the inner containment vessel after impacts with unyielding targets at speeds typical of a Category V impact accident. Several containment vessels exhibited minor damage for Category VI impacts, but no verified release occurred (NRC 1977).

F.4.4.3 *Package Release Fractions*

The release fraction is defined as the fraction of the RAM in a package that could be released from that package during an accident of a certain severity. Release fractions take into account all mechanisms necessary to create a release of RAM from a damaged package to the environment. Release fractions vary according to the package type. Type B packaging are designed to withstand the forces of severe accidents and, therefore, have smaller release fractions than Type A packaging. Plutonium packages are designed to even higher standards.

In a given accident involving a number of packages transported together, some of the packages could release part of their contents while others could have no release at all. The approach taken in an accident severity categorization scheme is to derive an estimate for the average release fraction for each severity category to support the assumption that all such packages in a shipment respond in the same way.

Release fractions for accidents of each severity category are given in Table F.4.4.3–1 for the package types considered in this appendix.

Note that the release fraction levels out at 100 percent for highest severity accidents. Since 82 percent of aircraft accidents are level III or less, as compared to 98 percent of truck accidents, the probability of a large release due to aircraft accidents is not much higher than that for truck accidents. For this reason, as well as the much higher frequency of truck accidents, aircraft accidents are screened from further analysis (Rhyne 1997).

TABLE F.4.4.3–1.—*Estimated Release Fractions for Shipping Packaging Under Various Accident Severity Categories*

SEVERITY CATEGORY	ESTIMATED RELEASE FRACTION	
	TYPE A	TYPE B
I	0	0
II	0.01	0
III	0.1	0.01
IV	1.0	0.1
V	1.0	1.0
VI	1.0	1.0
VII	1.0	1.0
VIII	1.0	1.0

Source: NRC 1977

F.4.4.4 *Respirable Fractions*

Subsequent to release, dispersion of the material into the atmosphere as an aerosol and, in most cases of interest, inhalation into the respiratory tract (respirable aerosols only) would be required to produce a significant exposure to members of the public. Therefore, in addition to determining the respirable fractions, the portion of that release which is respirable is also determined for risk analysis. Most solid materials are relatively nondispersible. Conversely, gaseous materials are easily dispersed. Liquid dispersibility depends on the liquid volatility. The aerosolization and respirable fractions depend on the physical form of the material.

The bounding off-site shipments described in subsection F.6.5.1 are plutonium powders. (The specific application of this methodology to the bounding shipments is also discussed in section F.6.5.1.) Generally the powder is pressed, reducing its dispersibility, and enclosed within four layers of metal containers: two associated with the plutonium packaging and two associated with handling outside the packaging. Should these four layers of containment fail in an impact accident, the mechanisms for converting the powder to a respirable aerosol would be the impact force itself and the release of gases.

Radioactive decay and solar insulation produce heat that causes gas within containers (including chemically inert gases, such as argon) to expand, thus raising the gas pressure inside the packaging. In addition to producing heat, radioactive decay produces helium, which further increases pressure. The average atmospheric pressure at LANL is 11.3 pounds per square inch absolute (psia), in contrast to 14.7 at sea level. The total pressure difference between the inner powder container and the environment from these factors can be as high as 30.1 psig. Tests with air injected into the bottom of a powder bed in an open-top container produced respirable fractions of 3×10^{-5}, 6.7×10^{-4}, and 6.1×10^{-4} for pressures of 9, 17.5, and 24.5 psig, respectively (DOE 1994b). The highest of the three values was used in this appendix. The fraction of powder aerosolized by depressurization is about a factor of 20 higher than the fraction aerosolized by impact forces (DOE 1994b) and the latter can be ignored in comparison to the former.

The use of the value of 6.7×10^{-4} for the respirable fraction of a release in this appendix is conservative since the four containment vessels would not be expected to completely open up, even in a severe impact accident.

Given an accident involving fire, the release mechanism would also be rapid depressurization since the packaging would contain no combustible material. Once a pathway from the powder cans to the environment is established, some additional powder may be aerosolized by updrafts from the fire. Review of DOE Handbook 3010-94 (DOE 1994b) shows that the depressurization effect is about 400 times larger than the updraft effect and the latter can be ignored in comparison to the former.

Exposure of a plutonium package to a 1,475°F fire for 30 minutes would produce a gas pressure of 64.5 psig in a container that has a rupture pressure of 123 psig (Barklay 1983). Longer fires would produce higher gas pressures and lower rupture pressures; therefore, the gas pressure at rupture would be no higher than 123 psig.

Table 4–12 in DOE Handbook 3010-94 (DOE 1994b) presents respirable fraction estimates from the aforementioned pressurized powder release tests for pressures of 9, 18, 24.5, 250, and 500 psig. For 250 psig, the maximum respirable fraction of a release is 2.5 x 10^{-2}. This value is judged to be conservative for the present case, because the test pressure was a factor of 2 higher than the expected package burst pressure and the tests involved blowing powder out of an open-topped container with a burst of air injected at the bottom of the powder bed.

The impact and fire values are combined for the RADTRAN severity categorization scheme by considering that fires occur in 1.6 percent of all truck accidents. The weighted value of the respirable fraction is then (0.984)(6.7 x 10^{-4}) + (0.016)(2.5 x 10^{-2}) = 1.06 x 10^{-3} for an open-top container. Table F.4.4.4–1 shows the results of combining the open-top container value of 1 x 10^{-3} with the Type B package release factors of Table F.4.4.3–1. The values for WIPP packaging, obtained by a similar analysis (DOE 1990), are also shown in Table F.4.4.4–1.

F.4.4.5 *Health Risk Conversion Factors*

The risk from ionizing radiation consists mostly of some number of excess latent cancer fatalities (LCFs). These are cancers resulting from, and that develop well after, the exposure to ionizing radiation. These represent an increase in the number of fatal cancers that occur from other causes. The excess LCF is the product of the dose and the risk conversion factor. The reader should recognize that these estimates are

TABLE F.4.4.4–1.—*Estimated Respirable Release Fractions for Shipping Packaging Under Various Accident Severity Categories*

[b] *Source:* DOE 1990

intended to provide a conservative measure of the potential impacts to be used in the decision-making process and do not necessarily portray an accurate representation of actual anticipated fatalities. In other words, one could expect that the stated impacts form an upper bound and that actual consequences could be less, but probably would not be worse. Refer to appendix D, section D.1 for further discussion of the determination and application of risk factors for LCFs.

The health risk conversion factors used throughout this appendix to estimate the number of expected cancer-caused fatalities due to radiological exposures are 5.0×10^{-4} cases of expected excess LCFs per person-rem for members of the public, and 4.0×10^{-4} cases per person-rem for workers (ICRP 1991).

F.4.5 Event Tree Analysis

Event trees are used for the analyses of off-site accidents involving HAZMAT transportation and on-site accidents involving RAM transportation.

An event tree is a graphical model for identifying and evaluating potential outcomes from a specific initiating event. The event tree depicts the chronological sequence of events (accident scenario) that could result from the initiating event. The identification of accident scenarios are the first of two key results from the event tree analysis; quantification of the scenario frequencies from the event tree is the second key result.

Figure F.4.5–1 is a graphical representation of five accident scenarios. The frequency of an accident producing a puncture force is designated as the parameter A, which is inserted on the tree as illustrated in Figure F.4.5–1. The conditional probability that puncture force causes package failure designated as the parameter B. Because B is the conditional probability that puncture force causes package failure, then 1-B is the conditional probability that puncture force does not cause package failure. The parameter C designates the conditional probability that a fire occurs, and the parameter D is the conditional probability that the fire duration is sufficient to cause package failure. The frequency of a particular scenario (e.g., puncture failure without fire, which is designated as F_2), is evaluated by multiplying the initiating event frequency and the individual probabilities, [e.g., $F_2 = A \times B \times (1 - C)$].

The parameter A is the product of the accident rate from section F.4.2.3 and the fraction of the accidents producing puncture force. The latter is taken from Dennis et al or Clarke et al., as appropriate. The parameter C and the probabilistic force magnitude distributions needed to evaluate parameters B and D are from the same two references.

Event trees similar to Figure F.4.5–1 are used for impact, crush, puncture, and fire without mechanical forces. This approach is conservative because the failures from other mechanical forces are not excluded for failure from the specific mechanical force. Clearly, the package can fail only once and the mechanical failures are triple counted. The error is generally less than a few percent, but the event trees are greatly simplified. The simple form for each force results from the assumption that all failures for a single accident force can be aggregated for frequency analysis. In frequency analysis, one package failure mode for a particular transportation accident force usually dominates the others. Event trees for fixed facilities are generally more complicated than transportation event trees because there are usually more opportunities for safety systems or operator action to mitigate the accident initiator.

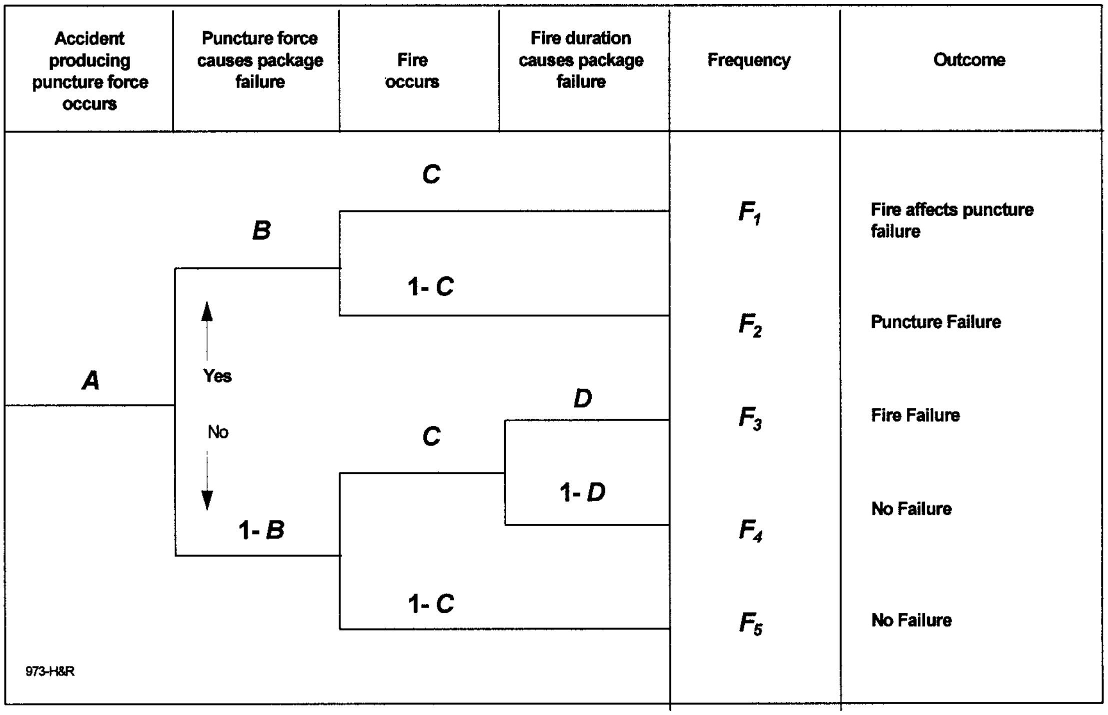

FIGURE F.4.5–1.—*Event Tree Analysis of Puncture Accidents.*

F.5 DETERMINATION OF SHIPMENTS BY ALTERNATIVE

F.5.1 Introduction

The determination of shipments of RAM and HAZMAT proceeded in three steps. First, historical databases were examined to get an overview, focus the subsequent data gathering to the most important risk contributors, and provide an accuracy check for the data-gathering process.

Data gathering, the second step, consisted of both interviews with cognizant persons and reviews of additional databases. The data-gathering process for RAM involved different databases, interviewees, and interviewers than the data-gathering process for HAZMAT.

The last step was the tabulation of results for each SWEIS alternative.

F.5.2 Baseline Shipments

DOE tracks unclassified shipments in a database called the Shipment Mobility/ Accountability Collection (SMAC). The tracking is based on shipping invoices paid by DOE and its contractors. Data on approximately 5,000 RAM and HAZMAT shipments to or from LANL were obtained from the SMAC for fiscal years 1990 through 1994. The shipments were first aggregated into 81 commodity groups, e.g., paint. The least HAZMAT were determined on the basis of the material maximum shipment weight compared with regulatory reporting thresholds in 40 CFR 302, Table 302.4, or 40 CFR 355, appendices A and B. The material was screened from further consideration if the maximum shipping amount was less than the threshold.

The remaining materials were grouped into four categories: radioactive, toxic, flammable, or explosive materials. A bounding material was picked as the most hazardous for each of these four groups on the basis of the toxicity of materials shipped in large amounts to or from LANL. The results are shown in Table F.5.2–1. Also shown in Table F.5.2–1 are the numbers of large and small shipments over the 5-year period. A large shipment is one that is greater than 10 percent of the maximum shipment quantity.

The materials screened from further consideration because of their low hazard are not listed in Table F.5.2–1. Some classified shipments, e.g., SST shipments, are also not included in Table F.5.2–1, since an invoice is not submitted for payment, however, classified shipments are considered in the risk analyses.

A recent annual shipment summary prepared by LANL is shown in Table F.5.2–2. Off-site shipments of RAM and HAZMAT total 3,526 per year in contrast to the SMAC results (Table F.5.2–1) of about 1,000 per year (when the screened shipments are considered). The large difference is due to the classified shipments mentioned previously and to other shipments for which LANL is not billed explicitly for transportation (e.g., contaminated-laundry shipments). Table F.5.2–2 was used to determine the number of HAZMAT shipments used in subsection F.5.3, and Table F.5.2–1 was used to help characterize those shipments

F.5.3 Shipments For SWEIS Alternatives

The determination of shipments by SWEIS alternative focused on ensuring that shipments were identified of both RAM and HAZMAT that could contribute significantly to accident risk. For example, bulk gas shipments were of special interest.

The RAM shipment characteristics were determined by interviewing cognizant LANL staff. Historical shipment data, on-site and off-site, were used to help ensure completeness. On-site shipments of SNM at the gram level were not individually accounted for because their contribution to risk would be minor; however, shipment projections were conservatively high to ensure that the transportation risks were bounded in this analysis. The off-site and on-site RAM shipments for each LANL SWEIS alternative are listed in Tables F.5.3–1 and F.5.3–2, respectively. The number of shipments projected is higher than those reflected in Table F.5.2–2 for a variety of reasons, including: the conservatism applied to shipment projections, the fact that several activities at LANL have been operating below planned levels, and the fact that some programs at LANL are increasing activity levels over recent levels due to DOE decisions made prior to this SWEIS (e.g., stockpile stewardship in the absence of underground testing, demonstration of accelerator production of tritium, and surveillance of stored materials).

The conservatism applied to the shipments is reflected in two ways. First, the number of shipments per year reflected in the table is typically at the high end of a range; this is done to ensure that impacts associated with total mileage are not underestimated. Second, the number of packages in a shipment is at the high end of a range; this is done to ensure that impacts associated with the shipment quantities (e.g., accidents that release cargo and worker and public exposures under no-incident conditions) are not underestimated. These shipments should not be used to estimate material flows/balances because the combination of bounding shipment numbers and bounding packages per shipment would yield overly conservative material flows. For those interested in such balances, the No Action Alternative would result in an average annual plutonium inventory increase of about 130 kilograms. The other alternatives would have slightly different average annual flows, but the inventory growth over the next 10 years can be accommodated in storage facilities, once the NMSF at TA–55 is operational. The enriched uranium inventory at LANL may actually

[a] Refer to the packaging section F.2.0.
[b] The total number of shipments over 10 years is listed. The annual total is the value divided by 10.
[c] This reflects return of recovered plutonium to RFETS. It is possible that this material would remain at LANL, as reflected in the *Final Environmental Impact Statement on Management of Certain Plutonium Residues and Scrub Alloy Stored at the Rocky Flats Environmental Technology Site* (DOE/EIS-0277) (DOE 1998).
[d] This surplus material is expected to leave LANL, eventually; however, without a site selection for the plutonium disposition program, the timing and location for such shipments is unknown. Except for material shipped as MOX fuel (see below), this material is expected to remain at LANL for the period addressed in the SWEIS.
[e] The shipments to Y–12 exceed the receipts from Y–12 because of an excess inventory that currently exists at LANL. This excess inventory of material from a variety of research and development activities is expected to be reduced over the next several years, at which point the HEU received will be approximately equal to the HEU shipped out.
RFETS = Rocky Flats Environmental Technology Site, SRS = Savannah River Site, LLNL = Lawrence Livermore National Laboratory, CMR = Chemistry and Metallurgy Research, HEU = highly enriched uranium, CSA = canned subassembly, STCs = standard transportation containers, NTS = Nevada Test Site, BNL = Brookhaven National Laboratory, HRL = Health Research Laboratory

[c] The total number of shipments over 10 years is listed. The annual total is the value divided by 10.
CSA = canned subassembly; MC&A = Materials Control and Accountability; STCs = standard transportation containers

decrease over time as the excess material in the current inventory is shipped off site.

The HAZMAT shipments were determined primarily by using LANL databases such as the Automated Chemical Inventory System (ACIS) and STORES as well as by using the SMAC data. Large inventories and bulk shipments were of special interest. When such inventories and bulk shipments were identified, responsible personnel were interviewed. The bounding historical material types and quantities identified in Table F.5.2–1 were validated for the toxic and explosive material categories. The bounding flammable material was changed from hydrogen to propane because the potential consequence of a propane release was determined to be larger as a result of the differing dispersion characteristics of lighter-than-air hydrogen and heavier-than-air propane (subsection F.6.5.4). The maximum future explosive shipment size for truck was determined to be 40,000 pounds (18,000 kilograms). Explosive shipments this large have been received in the past and could be received in the future.

An extensive analysis of on-site HAZMAT shipments determined that the large toxic, flammable, and explosive off-site shipments bound the accident risk both on site and off site.

Off-site shipments of toxic and flammable material classes were assumed to increase from the values in Table F.5.2–2 and vary with the SWEIS alternatives in the same way the off-site RAM shipments increase from the values in Table F.5.2–2 and vary with the SWEIS alternatives as described in Table F.5.3–1.

Although the number of many types of operational shipments associated with the Reduced Operations Alternative are lower than in the other alternatives, the number of low-level waste (LLW) shipments for off-site disposal increases substantially as compared to the number of LLW shipments under the No Action Alternative (since the Reduced Operations Alternative reflects off-site disposal of most LLW). This results in a total for off-site shipment mileage under the Reduced Operations Alternative, which is greater than the total off-site shipment mileage under the No Action Alternative. For this reason, the impacts that depend on the total off-site or radioactive shipment mileage are higher under the Reduced Operations Alternative than under the No Action Alternative.

The baseline value of off-site shipments in Table F.5.2–2 is the starting point for HAZMAT off-site shipments, after it is adjusted upward by the ratio of RAM shipments in Tables F.5.2–2 and F.5.3–1. In the case of toxic and flammable materials, the values are then adjusted for the SWEIS alternatives by the ratio of the number shipments under Expanded Operations, Reduced Operations, and Greener Alternatives to the No Action shipments in Table F.5.3–1. Projections, by alternative, were available for large off-site shipments of explosives. The on-site HAZMAT shipments were assumed to increase from the values in Table F.5.2–2 and vary with SWEIS alternatives in the same way as the on-site RAM shipments increase from Table F.5.2–2 to Table F.5.3–2 and vary with SWEIS alternative.

The resulting annual number of significant HAZMAT shipments for each alternative are given in Table F.5.3–3. The ratio of significant to total shipments is the same as that in Table F.5.2–1. As before, a large shipment is one that is greater than 10 percent of the maximum shipment quantity.

F.6 IMPACT ANALYSIS RESULTS

F.6.1 Introduction

To determine the impacts of the transportation of RAM and HAZMAT, four risk measures are defined in subsections F.3.3 and F.3.4: truck emissions in urban areas, truck accident injuries and fatalities that are independent of the nature

TABLE F.5.3–3.—*Annual Number of Hazardous Material Truck Shipments for SWEIS Alternatives*

SHIPMENT TYPE	ALTERNATIVE							
	NO ACTION		EXPANDED OPERATIONS		REDUCED OPERATIONS		GREENER	
	TOTAL SIGNIFICANT	TOTAL LARGE	TOTAL SIGNIFICANT	TOTAL LARGE	TOTAL SIGNIFICANT	TOTAL LARGE	TOTAL SIGNIFICANT	TOTAL LARGE
Off-Site, Toxic	645	90	1,439	200	606	84	645	90
Off-Site, Flammable	1,382	73	3,081	164	1,299	70	1,382	73
Off-Site, Explosive	518	2	1,155	2	487	1	518	1
On-Site	14,628	NA	34,231	NA	14,189	NA	15,068	NA

of the cargo, incident-free radiation exposure, and accidents resulting in a release of RAM or HAZMAT.

The RAM shipments presented by alternative (as in Tables F.5.3–1 and F.5.3–2) were identified for a specific origin/destination, or were categorized as going to one of five regions: northeast, southeast, northwest, southwest, or New Mexico. A centroid (central location) was picked for each of these regions on the basis of historical and projected shipments: Concord, Massachusetts; Aiken, South Carolina; Richland, Washington; Berkeley, California; and Albuquerque, New Mexico. The distances from LANL to the centroids are given in Table F.6.1–1. The shipment distances for explosives, flammable materials, and toxic materials were based on the corresponding large truck shipments in Table F.5.2–1. The centroids selected were Ft. Smith, Arkansas; Phoenix, Arizona; and Milwaukee, Wisconsin, respectively. All distances given in Table F.6.1–1 were determined from the HIGHWAY code (Johnson et al. 1993) and include the distances between LANL and I–25, as presented in Table F.4.3–1.

F.6.2 Truck Emissions in Urban Areas

The truck emission risk is based on 1.0 x 10^{-7} excess LCF per truck kilometer in urban areas where the number of kilometers is obtained as described in section F.4.3. Because Los Alamos is not an urban area, only off-site shipments were addressed in this analysis (off-site shipments by alternative are presented in Tables F.5.3–1 [RAM] and F.5.3–3 [HAZMAT]). The total distance traveled in urban areas in a year is calculated for these shipments using the distances in Table F.6.1–1, and the corresponding excess LCFs are calculated using the conversion factor presented above. The results are presented in Table F.6.2–1. Approximately 65 percent of the excess LCFs are due to RAM shipments and 35 percent are due to HAZMAT shipments. All shipments are conservatively assumed to result in an empty truck making the return trip. This is appropriate for WIPP shipments and many SST trailer shipments; however, most shipments are in general commerce and would not include the return of an empty truck.

TABLE F.6.1–1.—*Off-Site Shipment Distance per Trip*

ROUTE	MILES (KILOMETERS) IN URBAN AREAS	MILES (KILOMETERS) IN SUBURBAN AREAS	MILES (KILOMETERS) IN RURAL AREAS
Northeast, RAM	63 (102)	511 (823)	1,647 (2,652)
Southeast, RAM	20 (32)	275 (442)	1,312 (2,113)
Northwest, RAM	17 (27)	118 (190)	1,092 (1,759)
Southwest, RAM	20 (32)	75 (120)	1,094 (1,762)
Toxic Material	22 (36)	152 (245)	1,230 (1,981)
Flammable Material	13 (21)	50 (80)	496 (799)
Explosive Material	6 (10)	63 (102)	684 (1,102)

TABLE F.6.2–1.—*Number of Excess Latent Cancer Fatalities Due to Truck Emissions in Urban Areas*

RISK MEASURE	ALTERNATIVE			
	NO ACTION	EXPANDED OPERATIONS	REDUCED OPERATIONS	GREENER
Excess LCF per Year	3.2×10^{-2}	6.6×10^{-2}	3.4×10^{-2}	3.6×10^{-2}

F.6.3 Truck Accident Injuries and Fatalities

The HIGHWAY code (Johnson et al. 1993) was used to determine the distance traveled in each state for each of the centroids described in subsection F.6.1. The truck accident fatality, injury, and total accident rates in each state were taken from Saricks and Kvitek (1994). The rates in Table F.4.2.2–1 were used between Santa Fe and LANL, and the rates in Table F.4.2.3–1 were used on site. The results are given in Tables F.6.3–1 through F.6.3–3 for fatalities, injuries, and total accidents, respectively. Approximately 65 percent of the impacts are due to RAM shipments, and 35 percent are due to HAZMAT shipments. Again, all shipments are assumed to result in a return by an empty truck.

F.6.4 Incident-Free Radiation Exposure

The RADTRAN and ADROIT codes are used with the estimated number of off-site shipments in Tables F.5.3–1 and F.5.3–2 and with the estimated package surface radiation levels to obtain the results shown in Tables F.6.4–1 through F.6.4–4. The aircraft segment is for overnight carrier service; the truck segment to/from the airport is included in the truck results.

MEI dose occurs between LANL and I–25 and is 3.0×10^{-4}, 3.8×10^{-4}, 3.2×10^{-4}, and 3.4×10^{-4} rem for the No Action, Expanded Operations, Reduced Operations, and Greener Alternatives, respectively.

F.6.4.1 *Driver Doses from On-Site Shipments of Radioactive Materials*

The number of on-site shipments of RAM for the baseline year 1994, was 1,187 shipments, (taken from Table F.5.2–2). The baseline number of on-site shipments of RAM for the four SWEIS alternatives was taken from Table F.5.2–3. Table F.6.4.1–1 presents a summary of the total number of on-site shipments for all alternatives.

Dosimetry data for 25 on-site LANL drivers were provided by LANL. For identification purposes, the drivers were assigned numbers 1 through 25. Driver doses for 1994 were extracted from the dosimetry data package and are summarized in Table F.6.4.1–2. Driver number 2 did not have any dosimetry data for years beyond 1992, therefore, it was assumed that this driver is no longer working at LANL. He was dropped from further analysis. The driver doses were, therefore, based on 24 drivers.

To evaluate driver doses for the different SWEIS alternatives, it was assumed that the number of drivers (24) would be the same under each of the alternatives. In calculating the cancer risk associated with these doses, a dose-to-risk conversion factor 4×10^{-4} excess LCFs per person-rem was used (ICRP 1991).

To evaluate doses associated with on-site shipments for the different alternatives, the following procedure was followed:

- A dose per shipment was calculated for the baseline year as follows:
  - — Dose (person-rem per shipment) = (total collective dose) per number of shipments.
    $= 9.57 \times 10^{-4}$
  - — The baseline total dose of 1.136 person-rem was taken from Table F.6.4.1–2.
  - — The total number of shipments for each alternative was then multiplied by 9.57×10^{-4} to obtain the total collective dose per alternative.
  - — The total dose per alternative was then divided by 24 (the number of drivers) to obtain the average driver dose for each alternative.

TABLE F.6.4.1–1.—*Annual Doses and Cancer Risks to Drivers from On-Site Shipment of Radioactive Materials*

	BASELINE (1994)	NO ACTION	EXPANDED OPERATIONS	REDUCED OPERATIONS	GREENER
Number of Shipments	1,187	4,372	10,754	4,454	4,728
Collective Driver Dose (person-rem)[a]	1.136	4.184	10.292	4.262	4.525
Average Driver Dose (rem)[b]	0.047	0.174	0.429	0.178	0.189
Cancer Risk[c]	4.54×10^{-4}	1.67×10^{-3}	4.12×10^{-3}	1.70×10^{-3}	1.81×10^{-3}

[a] This is the total collective dose to all 24 drivers working at LANL. This dose was obtained by multiplying the total number of shipments by 9.57×10^{-4}.
[b] This is the annual average dose to each of the 24 drivers, obtained by dividing the total dose by 24.
[c] This is the sum of the excess LCF to all drivers from exposure to low level radiation. A dose-to-risk conversion factor of 4×10^{-4} is used.

TABLE F.6.4.1–2.—*Driver Dose Data for On-Site Shipments in 1994*

DRIVER NUMBER	SKIN DOSE (REM)	DEEP DOSE (REM)	NEUTRON DOSE (REM)	TOTAL DRIVER DOSE (REM)
1	0	0	0	0
2[a]	—	—	—	—
3	0	0	0	0
4	0	0	0	0
5	0	0	0	0

18	0.216	0.163	0	0.379
19	0.013	0	0	0.013
20	0.116	0.01	0.059	0.185
21	0.029	0	0	0.029
22	0	0	0	0
23	0	0	0	0
24	0.03	0	0.015	0.045
25	0.014	0.014	0	0.028
Total Collective Dose (person-rem/year)	0.688	0.356	0.092	1.136
Average Driver Dose (rem/year)	0.029	0.015	0.004	0.047

[a] No 1994 dosimetry data were available for driver No. 2. It was assumed that the driver left the job prior to 1994, and therefore he was dropped from the analysis.

— The collective driver dose was multiplied by a dose-to-risk conversion factor of 4 x 10^{-4} (cancer deaths per person-rem) to obtain the cancer risk.

The results for driver doses and associated risks are presented in Table F.6.4.1–1. The average driver doses are well below the DOE radiation protection standard of 5 rem per year. The highest collective dose (under the Expanded Operations Alternative) is just over 10 person-rem per year. The cancer risk associated with this dose is 4.12×10^{-3} excess LCFs per year.

F.6.5 Accidents

Analyses are conducted for scenarios leading to the release of either RAM or HAZMAT. The materials selected for analysis are those that represent bounding risks. Results are given for off-site shipments of RAM and HAZMAT. This subsection concludes with results for on-site RAM shipment.

F.6.5.1 *Determination of Bounding Materials*

Selection of the bounding material shipments is described in the following subsections.

Radioactive Materials

The shipments described in Tables F.5.3–1 and F.5.3–2 were evaluated as described in this subsection to determine those that would likely present the largest risk. These are referred to as the bounding materials. To determine the transportation risk, the shipment of bounding materials is evaluated in more detail. The bounding materials are those that have the largest value of

$$MAR \times ARF \times RF \times ID, \qquad (F–4)$$

Where:

MAR = material at risk (gram),

ARF = airborne release fraction,

RF = respirable fraction, and

ID = inhalation dose conversion factor (rem per gram).

The ARF values used are the RADTRAN default values, e.g., 1 x 10^{-6} for bulk metal, 1 x 10^{-2} for chunks, 1 x 10^{-1} for powder, and 1.0 for gases and volatile liquids. The RADTRAN default value for RF is 1.0 for gases and volatile liquids and 0.05 otherwise.

The bounding shipments determined by this approach are as follows:

- Off-site in an SST, plutonium-238 oxide powder (Table F.5.3–1, entries for plutonium operations and plutonium-238 heat source shipments to SRS)
- Off-site, americium-241 standards (Table F.5.3–1, americium-241 standard sales entry)
- On-site, plutonium-238 solution samples (Table F.5.3–2, entries for weapons grade plutonium and plutonium-238 liquid samples)

Equation F–4 is for materials that are hazardous due to their dispersion and subsequent exposure of persons to the airborne material. Another hazard is direct radiation from irradiated targets should the packaging fail (entry for irradiated targets in Table F.5.3–2). This hazard is bounding for its type. Some shipments associated with the Dual Axis Radiographic Hydrodynamic Test (DARHT) Facility are explosively configured, and the quoted values for ARF do not apply. DARHT shipments were not considered explicitly as bounding material; instead, the results from the DARHT EIS (DOE 1995) were incorporated into subsection F.6.5.5.

Risk includes both the consequence and the frequency of an event (subsection F.3.2). The bounding shipments were selected to produce the highest calculated consequence. The frequency associated with the calculated bounding consequence is determined by adding together the number of bounding shipments and any other shipment that has a consequence (as estimated by using Equation F–4) that is greater than 10 percent of the bounding consequence. This approach is conservative and is used for both RAM and HAZMAT shipments.

Shipments of CH TRU to WIPP exceed the 10 percent criterion and would be included in the frequency term for off-site shipments of americium-241 standards, but RH TRU shipments do not exceed the 10 percent criterion. Both shipment types are analyzed explicitly in this appendix because of the potential public interest in the results. Off-site shipments of pits in an SST trailer were also analyzed explicitly for the same reason.

Off-site shipments of plutonium-238 oxide powder in an SST trailer were conservatively aggregated with other strategic nuclear material also shipped in SST trailers. (ADROIT analyses of SST shipments were provided by SNL).

On-site shipments of some activated components (e.g., beam stops) as a result of accelerator operations exceed the 10 percent criterion and are included in the frequency term for on-site shipments of irradiated targets, as are DARHT shipments. (Some activated components may exceed the radiation level for irradiated targets, but irradiated targets are judged to pose the greater risk due to the packaging.)

On-site shipments of weapons-grade plutonium solution samples are included in the plutonium-238 solution samples frequency term.

Description of Bounding Radioactive Material Shipments

Pressed plutonium-238 oxide powder is enclosed in a welded capsule that is then enclosed in a welded vessel. The vessel is loaded into the 5320 packaging described in subsection F.2.4.5. Powder is transported to LANL from the Savannah River Site (SRS) in an SST. The 5320 package limit is 12.6 ounces (357 grams) of plutonium, but 15.6 ounces (441 grams) (17.6 ounces [500 grams] as plutonium dioxide) was used in the analysis to allow for possible increases in loading with another package.

The FL-Type container described in subsection F.2.4.1 is used to transport pits in an SST.

Up to 1 ounce (28 grams) americium-241 may be shipped in oxide form in a 30-gallon (114-liter) 6M package (subsection F.2.4.4); up to four packages may be shipped at a time. The oxide is enclosed in a stainless steel vial with a screw top and the vial is enclosed in a crimped can. This assembly is then placed in a 2R container in the 6M package.

Wastes transported to WIPP are enclosed in either the TRUPACT–II packaging described in subsection F.2.4.2 or the 72–B cask described in subsection F.2.4.6. One 72–B cask or three TRUPACT–II packages are transported in a single shipment. The waste parameters are those used in the WIPP Draft Supplemental EIS (DOE 1990c); additional details can be obtained from that document.

Samples of plutonium-238 in solution are transported from the Chemistry and Metallurgy Research (CMR) Facility to TA–55 in an armored vehicle that carries one to four packages. Each package consists of a stainless steel container enclosing three 0.5-gallon (2-liter) bottles. Each bottle is double sealed in plastic bags. The maximum concentration is 0.07 ounce (2 grams) plutonium-238 per 0.5-gallon (2-liter) bottle; all shipments are conservatively assumed to be at the maximum concentration. The LANL roads used are closed to traffic during the shipment.

The irradiated target package is a cylinder measuring 44 inches (112 centimeters) high, with a 26-inch (66-centimeter) diameter. The packaging is constructed of 5.8 tons (5.266 kilograms) of depleted uranium, lead, and stainless steel. The package is equipped with a sliding door on the bottom so that targets can be loaded into the packaging by means of special remote handling tools. The package is transported on a dedicated truck that has a keyhole-shaped receptacle recessed into the bed.

F.6.5.2 *Analysis of Off-Site Accidents Producing Bounding Radioactive Materials Releases*

The RADTRAN and ADROIT codes were used to analyze the bounding off-site RAM shipments described in subsections F.6.5.1. The MEI doses do not vary with route segment or alternative and are given in Table F.6.5.2–1 for each material analyzed with RADTRAN. ADROIT results that are separated into frequency and consequence components are not readily available. The product, MEI dose risk, varies with the number of shipments and the various shipment types. The population dose risks (consequence times frequency) and corresponding excess LCF risks are given in Tables F.6.5.2–2 through F.6.5.2–5 for each alternative.

F.6.5.3 *Analysis of Accidents Producing Chlorine Releases*

An event tree analysis produced the following accident scenarios that could lead to a major chlorine release:

- Release from a small hole caused by a puncture of the cylinder or failure of a valve from puncture or impact accidents
- Opening of a fusible plug as a result of fire
- Catastrophic failure in an impact accident
- Catastrophic failure as a result of a fire

The probability of each of these scenarios was determined from the event trees by using 1-ton (908-kilogram) container failure thresholds (Rhyne 1994a) and force magnitude probabilities (Dennis et al.). (Although LANL is not expected to store or handle chlorine containers this large, they have in the past, and the risks associated with transport of this size container bound the risks of toxic material shipments.) The ALOHA computer model (NSC 1995) was used to estimate release rates from the 1-ton (908-kilogram) container, and the DEGADIS (Havens and Spicer 1985) dense gas dispersion model was used to predict downwind chlorine concentrations following the four postulated releases. (A separate version of DEGADIS is used because the version incorporated in ALOHA does not readily provide time variation of downwind concentrations.)

In this analysis, exposures to toxic chemicals are compared to Emergency Response Planning Guidelines (ERPGs). ERPGs are explained in detail in appendix G, section G.2.2. ERPG–2 is the maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to 1 hour without experiencing or developing irreversible or other serious health effects or symptoms that could impair their abilities to take protective action. ERPG–3 is the maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to 1 hour without experiencing or developing life-threatening health effects. The model predicts the length and width of the cloud for which concentrations are greater than those at ERPG–2 and ERPG–3. The area affected, the maximum exposure duration, the maximum downwind distance affected, and the maximum chlorine cloud width are shown in Table F.6.5.3–1 for the bounding release, which is release from a small hole with fire. (Catastrophic releases are of very short duration and a high escape fraction is likely.)

TABLE F.6.5.3–1.—*Exposure Parameters of Bounding Chlorine Accident*

ACCIDENT DESCRIPTION	MAXIMUM EXPOSURE DURATION (MINUTES)	MAXIMUM DOWNWIND DISTANCE (KILOMETERS)		MAXIMUM CLOUD WIDTH (KILOMETERS)	
		EPRG-2	EPRG-3	EPRG-2	EPRG-3
Fire Causes Opening of a Fusible Plug	8.4	4.2	2.1	0.28	0.15

EPRG = Emergency Response Planning Guideline

(NSC 1995) was used to estimate release rates from the 1-ton (908-kilogram) container, and the DEGADIS (Havens and Spicer 1985) dense gas dispersion model was used to predict downwind chlorine concentrations following the four postulated releases. (A separate version of DEGADIS is used because the version incorporated in ALOHA does not readily provide time variation of downwind concentrations.)

In this analysis, exposures to toxic chemicals are compared to Emergency Response Planning Guidelines (ERPGs). ERPGs are explained in detail in appendix G, section G.2.2. ERPG–2 is the maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to 1 hour without experiencing or developing irreversible or other serious health effects or symptoms that could impair their abilities to take protective action. ERPG–3 is the maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to 1 hour without experiencing or developing life-threatening health effects. The model predicts the length and width of the cloud for which concentrations are greater than those at ERPG–2 and ERPG–3. The area affected, the maximum exposure duration, the maximum downwind distance affected, and the maximum chlorine cloud width are shown in Table F.6.5.3–1 for the bounding release, which is release from a small hole with fire. (Catastrophic releases are of very short duration and a high escape fraction is likely.)

The number of fatalities or injuries would depend on the population density and the ability of people to avoid harmful exposure by going indoors or leaving the affected area. The frequency of occurrence of this accident would depend on the truck accident rate. The accident rate and population density would vary for the different route segments. The ability of people to avoid harmful exposure (to escape) would depend on various factors; an escape fraction of 0.98 is used for all route segments. This fraction is based on analysis of a transportation accident producing fatal releases of ammonia (Glickman and Raj 1992) and should be applicable to chlorine because the same dispersion coefficients apply, resulting in similar plume shapes and gradients of concentration. For both, there will be objectionable odor a short period prior to concentrations that have serious effects. The plumes tend to be visible and of modest transverse dimension, with very objectionable odor and strong respiratory irritation at their edges, permitting recognition and urging prompt escape on foot. The estimated frequency of a major chlorine release and the estimated number of associated fatalities and injuries are given in Table F.6.5.3–2 for different population densities along the routes. The risk values (i.e., annual frequency times consequences analogous to Tables F.6.5.2–2 through F.6.5.2–5) are given for the SWEIS alternatives in Table F.6.5.3–3.

F.6.5.4 *Analysis of Accidents Producing Propane Releases*

The bounding consequence from a propane release would be the generation of a fireball. The fireball would likely occur too soon after the postulated truck accident for evacuation to be effective. The fireball would have a radius of about 148 feet (45 meters) and would burn for about 3 seconds. Many persons would be protected by buildings or automobiles for this short duration. It is assumed that 50 percent of the available population would be shielded from the fireball, 10 percent would be fatalities, and the remainder would be injured (PNL 1980). In addition, fatal second-degree burns might be experienced out to a radius of 620 feet (189 meters). The percentages of available persons that would be exposed to the radiant heat flux are assumed to be 0.16 percent, 12 percent, and 19 percent in urban, suburban, and rural areas, respectively (PNL 1980).

TABLE F.6.5.3–2.—*Frequencies and Consequences of a Major Chlorine Release*

The number of fatalities or injuries would depend on the population density and the ability of people to avoid harmful exposure by going indoors or leaving the affected area. The frequency of occurrence of this accident would depend on the truck accident rate. The accident rate and population density would vary for the different route segments. The ability of people to avoid harmful exposure (to escape) would depend on various factors; an escape fraction of 0.98 is used for all route segments. This fraction is based on analysis of a transportation accident producing fatal releases of ammonia (Glickman and Raj 1992) and should be applicable to chlorine because the same dispersion coefficients apply, resulting in similar plume shapes and gradients of concentration. For both, there will be objectionable odor a short period prior to concentrations that have serious effects. The plumes tend to be visible and of modest transverse dimension, with very objectionable odor and strong respiratory irritation at their edges, permitting recognition and urging prompt escape on foot. The estimated frequency of a major chlorine release and the estimated number of associated fatalities and injuries are given in Table F.6.5.3–2 for different population densities along the routes. The risk values (i.e., annual frequency times consequences analogous to Tables F.6.5.2–2 through F.6.5.2–5) are given for the SWEIS alternatives in Table F.6.5.3–3.

F.6.5.4 *Analysis of Accidents Producing Propane Releases*

The bounding consequence from a propane release would be the generation of a fireball. The fireball would likely occur too soon after the postulated truck accident for evacuation to be effective. The fireball would have a radius of about 148 feet (45 meters) and would burn for about 3 seconds. Many persons would be protected by buildings or automobiles for this short duration. It is assumed that 50 percent of the available population would be shielded from the fireball, 10 percent would be fatalities, and the remainder would be injured (PNL 1980). In addition, fatal second-degree burns might be experienced out to a radius of 620 feet (189 meters). The percentages of available persons that would be exposed to the radiant heat flux are assumed to be 0.16 percent, 12 percent, and 19 percent in urban, suburban, and rural areas, respectively (PNL 1980).

The number of persons that would be affected depends on the population density; the frequency of the accident would depend on the truck accident rate. Both of these parameters would vary for the different route segments. The truck accident frequency of a major propane release and the estimated numbers of fatalities and injuries are given in Table F.6.5.4–1 for different population densities along the routes. The fatality and injury risks are given in Table F.6.5.4–2 for the four SWEIS alternatives. The frequency of large explosive shipments was added to the frequency of large flammable shipments.

F.6.5.5 *Analysis of On-Site Accidents Producing Bounding Radioactive Materials Releases*

The bounding on-site shipments involving RAM are the transport of plutonium-238 solution from CMR to TA–55 and the transport of irradiated targets from the LANSCE to TA–48. Both types of shipments are made with the roads closed to all persons except personnel directly involved in the transport. Therefore, no member of the public would be expected to be involved in the postulated truck accident or to be a bystander after the postulated truck accident.

MEI dose is calculated using the following assumptions. In the case of plutonium-238 solution, it is assumed that a person would stand very close to the evaporating liquid for 10 minutes before being warned away. In the case

TABLE F.6.5.4–1.—*Frequencies and Consequences of a Major Propane Release*

of the irradiated target cask failure, a narrow radiation beam would be produced that would be lethal after 10 minutes of continuous exposure at a distance of 6 feet (1.8 meters) from the cask, and it is assumed that a person would stand in this beam for 10 minutes.

The resulting MEI doses and frequencies are given in Table F.6.5.5–1, and MEI risk is given in Table F.6.5.5–2 for the four SWEIS alternatives. The plutonium-238 solution sample shipment frequency terms includes weapons-grade plutonium solution sample shipments, and the irradiated target shipment frequency term includes activated inserts and beam stops (Table F.5.3–2) shipments. DARHT shipment accidents could result in an off-site MEI dose of 76 rem and fatalities to LANL truck crews and other individuals within 80 feet (24 meters) of the explosion (DOE 1995). The frequency of DARHT shipments has been added to the frequency of irradiated target shipments.

F.6.6 Transportation of Waste Off Site

Transportation of waste is imbedded in the transportation risk assessment. Because the methodology is directed at identifying the greatest risks associated with shipments of materials, both from the standpoint of incident-free shipments as well as accidents, the lesser quantities of materials per package typically found in wastes (as compared to stock materials) tend to screen them from a detailed analytical presentation in this assessment. Waste shipments have been found to be of public interest; and it is useful, therefore, to discuss the manner in which the impacts of these shipments are considered. This qualitative presentation is also illustrative of the overall methodology.

Numbers of shipments of waste per year in the categories of radioactive and nonradioactive hazardous material were included in the mileage calculations for shipment of other materials in the same class for the purpose of evaluating impacts due to vehicle emissions, direct

TABLE F.6.5.5–1.—*Maximally Exposed Individual Doses and Frequencies for On-Site Radioactive Materials Accidents*

SHIPMENT TYPE	PER TRIP FREQUENCY	MEI DOSE
Plutonium-238 Solution	6.9×10^{-10}	8.7 rem
Irradiated Targets	3.4×10^{-8}	fatal

TABLE F.6.5.5–2.—*On-Site Radioactive Materials Accident Maximally Exposed Individual Risk*

SHIPMENT TYPE	MEI RISK PER ALTERNATIVE			
	NO ACTION	EXPANDED OPERATIONS	REDUCED OPERATIONS	GREENER
Plutonium-238 Solution	7.7×10^{-7} rem/year (3.1×10^{-10} excess LCF/year)	1.4×10^{-6} rem/year (5.8×10^{-10} excess LCF/year)	7.7×10^{-7} rem/year (3.1×10^{-10} excess LCF/year)	7.7×10^{-7} rem/year (3.1×10^{-10} excess LCF/year)
Irradiated Targets	3.1×10^{-6} fatalities/ year	3.2×10^{-6} fatalities/ year	2.9×10^{-6} fatalities/ year	3.2×10^{-6} fatalities/ year

exposure to radiation, and accidents not involving the release of cargo. Specifically, TRU waste shipments to WIPP are less than 10 percent of the total number of shipments under any alternative (and because of the relatively short distance between LANL and WIPP, these shipments would constitute an even smaller percentage contribution to incident-free impacts attributed to radioactive material shipments), LLW shipments for off-site disposal under the Reduced Operations and Greener Alternatives are about 30 percent of the total shipments under these alternatives (LLW constitutes about 15 percent and less than 1 percent of off-site shipments under the No Action and Expanded Operations Alternatives, respectively), and about 10 percent of the total number of hazardous (nonradioactive) shipments would be expected to be waste shipments. (This is based on historical information—hazardous waste shipments were not specifically projected and are not reflected as individual shipments in the off-site shipment projections in this appendix.) Although the numbers of hazardous waste shipments were not individually projected, they are included in the numbers of shipments in Table F.5.3–3 and considered in the total mileage and impacts projected for hazardous material shipments.

Routes for the shipment of waste are typical of, and represented by, the routes chosen for analysis that covered the U.S. by sector in terms of population density as well as the category of road (except that WIPP shipment routes, as noted above, are much shorter than most of the nonwaste radioactive material shipment routes); thus, the contribution of waste shipments to the total risks due to vehicle emissions and accidents without a cargo release could be estimated using the percentages in the previous paragraph (although this would be very conservative for WIPP shipments). The amount of material in a given container is orders of magnitude less for waste shipments than for product shipments (see accidents discussion below), so the incident-free radiation exposure attributable to waste shipments would be a very small percentage of that presented in this appendix and in chapter 5.

Accidents involving the release of cargo were based on factors such as the greatest quantity of the material known to be shipped, the most toxic, and the least protective packaging. Accident risk associated with the transportation of transuranic waste to WIPP was specifically analyzed and presented in this appendix and in chapter 5 due to public interest in such shipments, and they are not discussed further here. LLW and low-level mixed waste (LLMW) shipments involve, at most, from 0.001 percent (for plutonium-238) to 0.01 percent (for americium-241 and plutonium-239) of the total material considered in the off-site radioactive materials accidents specifically presented in this appendix. The mileage associated with LLW waste shipments is conservatively estimated at 30 percent of that used in the radioactive materials accident analyses presented in this appendix. Therefore, the risk associated with waste shipments is conservatively estimated to be 0.003 percent of that analyzed and presented for radioactive materials, as presented in this analysis.

Similarly, shipments of hazardous chemical (nonradioactive) waste contain much less of the hazardous material content than do the shipments of chlorine and propane analyzed and presented in this appendix and in chapter 5. While no estimates of waste contents were available for use in this SWEIS, such shipments would not be likely to exceed 10 percent of the amounts used for chlorine and propane accidents (and would likely be a much smaller fraction of these quantities). On that basis, hazardous chemical waste shipments, which constitute about 10 percent of the total number of hazardous chemical shipments, would not be expected (conservatively) to result in risks that exceed 1 percent of those presented in this SWEIS for hazardous material shipments.

F.7 ANALYSIS OF THE SANTA FE RELIEF ROUTE OPTION

F.7.1 Introduction

The effect of the proposed relief route would be to replace 6.5 miles (10.5 kilometers) on U.S. 84/285 through Santa Fe to exit number 282 of I–25 with 13.8 miles (22.2 kilometers) starting from U.S. 84/285 north of Santa Fe to exit number 276 of I–25, south of Santa Fe. Because of the location where the Relief Route meets I–25, travel on I–25 south of Santa Fe would be reduced by six miles of highway travel, and travel on I–25 north of Santa Fe would be increased by 6 miles of highway travel if the Relief Route were used. The route between exit number 282 of I–25 and the junction of U.S. 84/285 with NM 502 consists of 1.2 miles (1.9 kilometers) of urban, 3.9 miles (1.9 kilometers) of suburban, and 14.9 miles (24 kilometers) of rural highway (Table F.4.3–1). For this analysis, the 6.5 mile (10.5 kilometer) segment replaced is assumed to consist of all of the urban and suburban highway plus 1.4 miles (2.3 kilometers) of rural highway. The 13.8-mile (22.2-kilometer) relief route is assumed to consist of 9.6 miles (15.4 kilometers) of suburban and 4.2 miles (6.8 kilometers) of rural highway.

The four risk measures evaluated in section F.6 are evaluated in this section for the relief route option.

F.7.2 Results

The effect of the proposed relief route on truck emissions in urban areas would be to eliminate 1.2 miles (1.9 kilometers) of urban highway. The overall reduction in excess LCFs would be small, as shown in Table F.7.2–1.

A comparison of the annual number of fatalities and injuries from truck accidents is shown in Tables F.7.2–2 and F.7.2–3, respectively. The variation in truck accidents is shown in Table F.7.2–4.

Only the route segments affected by the relief route option are described. The effect of the relief route on the remainder of New Mexico route segment is negligible, but the effect on the U.S. 84/285 to I–25 route segment is reduced by about one-half for the relief route option. The reason is that the accident rate assumed on the relief route is approximately one order of magnitude less than that for some parts of the route through Santa Fe, in contrast to the distance which increases by 50 percent.

A comparison of the annual incident-free population doses for the No Action, Expanded Operations, Reduced Operations, and Greener Alternatives is given in Tables F.7.2–5 through F.7.2–8, respectively. In general, the changes are small with a few exceptions. The occupational and stops doses are directly proportional to the length and inversely proportional to the truck speed, and they increase for the relief route. The dose to those sharing the route is directly proportional to the traffic density, which is significantly reduced on the relief route. This dose decreases for the relief route.

A comparison of the change in accident frequencies is shown in Tables F.7.2–9 and F.7.2–10 for radioactive and HAZMAT, respectively. The change in the remainder of New Mexico route segment depends on whether the shipment direction is southwest or northeast. Chlorine is the representative material for all toxic materials, whose representative source is the northeast; and propane is the representative material for all flammable materials, whose representative source is the southwest. (The comment in the next paragraph about potential exaggeration applies to Tables F.7.2–9 and F.7.2–10.)

The changes in bounding RAM accident population dose risks are shown in Tables F.7.2–11 through F.7.2–14 for the four SWEIS

alternatives. The change in injury and fatality risks of major releases of chlorine and propane is shown in Tables F.7.2–15 through F.7.2–18 for the four SWEIS alternatives. The RADTRAN results in Tables F.7.2–11 through F.7.2–14 show a major increase for the remainder of New Mexico route segment, but the ADROIT results show no change. The difference in these sets of results is due to the difference in the way the portion of I–25 between exits 276 and 282 was modeled in the two computer programs. All of the RAM shipments analyzed in Tables F.7.2–11 through F.7.2–14, as well as chlorine shipments in Tables F.7.2–15 through F.7.2–18, are expected to follow I–25 north for 6 miles further with the relief route option than for the route through Santa Fe, in contrast to propane shipments that would go south on I–25 and experience 6 miles less travel on I–25. The RADTRAN, chlorine, and propane analyses are based on the conservative assumption that the 6 miles on I–25 are in an area with a population density characteristic of suburban areas. The changes in the remainder of New Mexico values for americium-241, CH TRU, RH TRU, chlorine, and propane are therefore somewhat exaggerated. The changes for the 6 miles on I–25 are accurately computed in the ADROIT analysis of plutonium-238 and pits, but are tabulated in the U.S. 84/285 to I–25 route segment rather than the remainder of New Mexico route segment. The ADROIT computer code has the capability to access population data at the census block level.

F.8 UNCERTAINTY AND CONSERVATISM IN THE ANALYSIS

The major steps in the transportation risk analysis are as follows:

- Determination of the amount and characteristics of materials that will be needed or generated and thus moved to or from the LANL site.
- Estimation of the amount per shipment (e.g., packaging requirements and efficiency of truck capacity utilization, which may conflict with other logistics considerations such as storage requirements until a truck can be filled).
- Determination of the bounding material in a category and the number of shipments of this and similar materials that should be aggregated for frequency analysis.
- Selection of appropriate origin and destination and determination of the route and its characteristic population, accident rate, etc.
- Estimation of package release probabilities.
- Estimation of the amount released from the packaging and the fraction airborne that is respirable.
- Calculation of dispersion, exposure, and health effect.

Uncertainties are associated with each step. The overall approach to dealing with uncertainty is to estimate conservative values for parameters and to estimate consistently. On the other hand, estimates are not knowingly chosen to be conservative by orders of magnitude because that approach could obscure differences between alternatives. The focus of this analysis was on shipments that could contribute significantly to the transportation risk. The total number of shipments is important, as are the shipments of large amounts of dispersible and toxic material. The following subsections contain descriptions of sources of uncertainty and the resulting conservatism for each of the major analysis steps. Emphasis is placed on uncertainty unique to the SWEIS.

F.8.1 Material Amount and Characterization

Because a detailed analysis of every type of LANL shipment would be impractical, shipments of similar types were aggregated on the basis of the most hazardous material.

Chemicals were grouped in classes of materials such as flammable materials. RAMs were grouped in many more categories. First, general categories such as LLW, pits, samples, and irradiated targets were used. Then the general categories were divided into groups within which significant packaging differences could occur. For example, LLMW transported on site was aggregated into three groups: materials likely to be packaged in 55-gallon drums, materials likely to be transported in bulk, such as in covered dump trucks (soil and debris), and materials likely to be transported in 96-cubic foot boxes (contaminated lead and non-RCRA waste).

The incident-free risk is proportional to the TI value. The maximum legal value of 10 millirem was used unless there were data to the contrary. The conservatism in TI estimation is significant because most shipments are much less than the regulatory maximum.

Some small shipments are likely to have been missed. For example, on-site shipment of small quantities of special nuclear materials and chemicals are thought to have been overlooked in the data-gathering activity. These small shipments have no effect on the risk of bounding accidents and would contribute little to the incident-free and truck-related risk measures. The net effect is a significantly conservative estimate.

F.8.2 Amount per Shipment

In almost all cases, the number of packages per shipment was selected as less than full use of the truck capacity. In the case of contaminated laundry, for example, the current one truckload per week (sometimes with less than full capacity) is assumed to continue and the number of laundry bags is assumed to vary with alternative and with week-to-week and year-to-year variability in operations. The only exception to weekly shipments is that the increase for the expanded alternative was large enough to change the projection from a shipment every five working days to one every three working days.

Another example of less than full truck capacity is the case of LLW transported off-site. A waste volume equivalent to 65, 55-gallon drums, with an 80 percent volume utilization, was used for both LLMW and for LLW consisting of soil and debris. A tractor-trailer can hold 80 drums if weight limits are not exceeded. The volume per shipment, 389 cubic feet (10.9 cubic meters), also corresponds to that of a standard covered dump truck, but larger trucks could also be used. LLMW would likely go to several facilities, and full truck loads could be impractical. On the other hand, soil and debris would likely go to the same facility (in a given time frame), and full shipments would be a realistic expectation.

The objectives were to be conservative, but not overly so, in estimating amounts per shipment and to be consistent across alternatives.

F.8.3 Bounding Materials

It is impractical to compute the accident risk from every shipment. As described in subsection F.6.5.1, the approach is to select bounding materials for consequence analysis. Selection of the bounding materials was based on quantity, dispersibility, and health effects. Selection of bounding chemicals was straightforward: the toxic or flammable bulk gases are the obvious primary candidates. Highly dispersible actinides are the primary candidates for RAM; dispersion is enhanced by the physical form; e.g., powder, or by the presence of another dispersion-causing material; e.g., explosives. Highly irradiated materials are in a separate category, as are fissile materials.

Estimates of the number of bounding shipments are less straightforward because the frequency of shipments of similar materials should also be included. Obviously, shipments of materials that are slightly less dangerous than the bounding material should contribute to the frequency component of risk. The question is, how much less dangerous? As described in subsection F.6.5.1, the measure of danger chosen was the amount of material, and if the amount exceeded 10 percent of the bounding amount, then the shipment was counted in the frequency term. This is a conservative approach. The term "amount" for RAM was considered as the product of the weight in grams, the respirable airborne release fraction, and the health risk conversion factor of rem per gram.

F.8.4 Origin and Destination

A major simplification was the aggregation of the numerous origin and destination cities (other than the LANL site) to only a few cities. Doing otherwise would have been impractical. The methodology introduced major conservatism in the route length of most shipments. The centroid city of each of the five regions was chosen so that the great majority of shipments were going to a city no farther away than the one chosen. First, the average HAZMAT shipping distance was determined for historical large shipments. Then a city in the northeast (toxic), southeast (explosives), and southwest (flammable) that was at that average shipping distance or farther from LANL was chosen. The conservatism introduced for HAZMAT shipments is likely much less than that for RAM shipments, because an average distance was computed for HAZMAT shipments, and a near-upper-bound distance was chosen on the basis of historical shipments for the RAM shipments.

The choice of SRS for the southeast centroid, when material has historically also been shipped to Florida, illustrates the logic underlying the choice of a near-upper-bound distance. Portions of Florida are farther from LANL than is SRS. However, approximately 94 percent of the historical ground shipments are to destinations no farther from LANL than is the SRS, and approximately 80 percent are to destinations significantly closer than the SRS. Therefore, choosing the upper bound distance (Florida) would be overly conservative because only about 6 percent of the shipments actually go to Florida. The logical choice is the near-upper-bound distance to the SRS.

Given the chosen city, no special conservatism was introduced when choosing other factors such as route, population density, or accident rate.

F.8.5 Package Release Probability

The package release probability is based on performance requirements for all packages of a given type (e.g., Type B). The package release probability used in this analysis would correspond to the release probability of a package meeting the minimum performance requirements for its type. The conservatism would have to be quantified on a package-specific basis and such quantification would require substantial analyses.

F.8.6 Package Release Fractions and Respirable Airborne Release Fractions

The package release fraction is also based on performance for all packages of a given type, and the conservatism would have to be quantified for a specific package and contents.

The respirable airborne release fraction used for analysis for general commerce shipments corresponds to that for a loose, noncombustible powder that suddenly loses all barriers preventing its release (i.e., its packaging suddenly becomes equivalent to an open-top container). In fact, the actual powder is not loose, but compressed, and the packaging is unlikely to fail such that a line-of-sight opening develops. Rather, realistic package failures are more likely to produce an indirect path to the environment that would significantly reduce the fraction that could be made airborne and respirable in the environment. The respirable airborne release fraction used is estimated to be conservative by several orders of magnitude. Further definite quantitative refinement of the value used is not practical given the variety of packaging and release mechanisms considered.

F.8.7 Dispersion and Exposure

Standard dispersion computer programs (RADTRAN, ADROIT, DEGADIS, and ALOHA™) were used with the programs' default or recommended meteorological input. To establish population densities, most exposure calculations were based on census data; time-of-day variation could increase or decrease these values. The chlorine accident escape fraction and propane accident shielding fractions are intended to be average values, but few data are available to support the values used. The MEI doses are intended to be upper bounds for the default meteorological conditions.

F.8.8 Summary

Four risk measures (section F.3) are used in this appendix and each has a consequence and a frequency component. Although the uncertainties described previously do not apply uniformly to the eight risk components, a general statement can be made that each risk component is much more likely to be significantly conservative than to be slightly not conservative enough. This statement applies to all alternatives. A major ramification of the conservatism is that shipments in addition to those described in Tables F.5.3–1 and F.5.3.2–3 are enveloped by the present analysis.

APPENDIX G
ACCIDENT ANALYSIS

G.1 INTRODUCTION

The NEPA decision maker and the stakeholders need to know the consequences of the different SWEIS alternatives. Some but not all of the consequences are those of the possible accidents. Accidents are defined as unexpected or undesirable events that lead to the release of hazardous material within a facility or into the environment (DOE 1996a), exposing workers and/or the public to hazardous materials or radiation.

There are two benefits from this SWEIS accident analysis. First, the analysis conservatively characterizes the overall risk posed by the operation, creating a context for the decision maker and putting the site in perspective for the public. Second, it quantifies the increment in risk among the several alternatives, as an input into the decision.

G.1.1 Characterization of the Risk from Accidents

Characterization includes a consideration of the type of the accident (e.g., fire, explosion, spill, leak, depressurization, criticality, etc.), the initiator (e.g., human error, chemical reaction, earthquake, strong wind, flood, vehicle accident, mechanical failure, etc.) the material at risk (e.g., plutonium, tritium, toxic chemical, explosives, inflammable gas, etc.). Characterization also considers the type of consequences of the accident (e.g., immediate fatalities, prompt reversible and irreversible health effects, latent cancers—some of which lead to eventual death), and the magnitude of the consequences (e.g., to workers only, to hypothetical members of the public, to a few, some or many real individuals off site, etc.). Finally, characterization considers the likelihood that an accident will occur.

Because LANL is a complex and diverse site, there are (as at any site) a wide range of accident scenarios that can be hypothesized, with a corresponding range of likelihoods and consequences, both realistic and imagined. For this SWEIS we analyze accidents that could result in the release of hazardous materials from particular facilities and operations. While such releases are not routinely expected, because controls are in place to prevent such releases or limit their consequences, there are many scenarios that could potentially end in such a release. The analyses in this SWEIS select the more probable scenarios.

To characterize the accident risk at LANL, this analysis has deliberately chosen a range of types of accidents and a range of consequences, including among these accidents for which the public has shown concern. This analysis does not attempt to identify every possible accident scenario, but instead selects accidents that characterize or dominate the risk to the public from site operations (referred to as risk-significant accidents). It thereby provides an objective context for the public to evaluate the risk posed by site operations and a context for the decision among alternatives.

Accident scenarios may be considered "risk-significant" when they pose risks that are significant in the context of the total risk posed by the site and when compared to other site accidents. The term "risk-significant" does not imply a threshold or particular magnitude of risk. If the risk posed by the site is small or very small, then a risk-significant accident at that site has a correspondingly small or very small risk.

By identifying the locations of appreciable quantities of hazardous material, the accidents associated with these materials can be assessed. By grouping these accidents according to their likelihood or frequency and the magnitude of their consequences, it is possible to select accidents for further characterization and qualitatively portray their relative risk. The accidents selected for this detailed analysis are those with bounding consequences as well as those that characterize the risk of operating LANL.

Such grouping or "binning" of accidents is illustrated in Figure G.1.1–1. Accidents assigned to bins within a row vary in terms of their consequences but not their frequencies. Accidents assigned to bins within a column vary in terms of their frequency but not their consequences. Accidents have an increasing level of risk going from left to right within a row or from bottom to top within a column. Accidents that are in the same bin have about the same risk. Thus, when accidents are considered within the context of this matrix, they can be compared qualitatively, and their relative risk ranking can be used for decision making.

There can be, however, a large number of different potential accidents or scenarios at a site such as LANL, especially of those in the high probability-low consequence bins (for example, minor industrial accidents). However, the risk changes exponentially as one goes from one column or row to another. Therefore, by selecting accidents with the highest consequences for a particular frequency row, the accidents that contribute the most to the overall risk to the public from site operations can be considered. Also, these accidents can be characterized by the type of material-at-risk, accident initiators, their scenario progression, and the type and magnitude of their consequences. In particular, the question can now be considered as to the degree by which the risk-significant accidents change across the alternatives. In other words, is there a decision within this SWEIS that could and should be influenced by a change in risk? Not until the potential accidents change, from at least one frequency range or consequence range to another, or accidents are added or deleted as a result of changes in mission and operations, does the risk profile for the site change significantly.

Any particular facility or inventory can be affected by a wide variety of accidents that may have about the same frequency and about the same consequences. For instance, some of the gases in cylinders at a gas cylinder storage facility can be released by fire or by impact from a variety of initial causes. All of these accidents might have similar frequencies and consequences, and so can be represented by a "representative accident." (In the analysis, the frequency of that representative accident might be increased to account for other initiators that lead to the same release.) Conversely, there may be at that storage facility, at times, a larger inventory of a particularly toxic gas whose probability of release is low but that would have larger consequences than releases of the other gases. This postulated accident would be a "bounding accident" whose consequences would not be exceeded with any reasonable possibility or probability. For purposes of a SWEIS, the bounding accidents are intended to provide an envelope that captures variations in routine operations and inventories whose details cannot be predicted.

These representative and bounding accidents characterize the many accidents that could be postulated for that material or facility. There would be no benefit gained in a SWEIS from analyzing each of the many accidents so characterized.

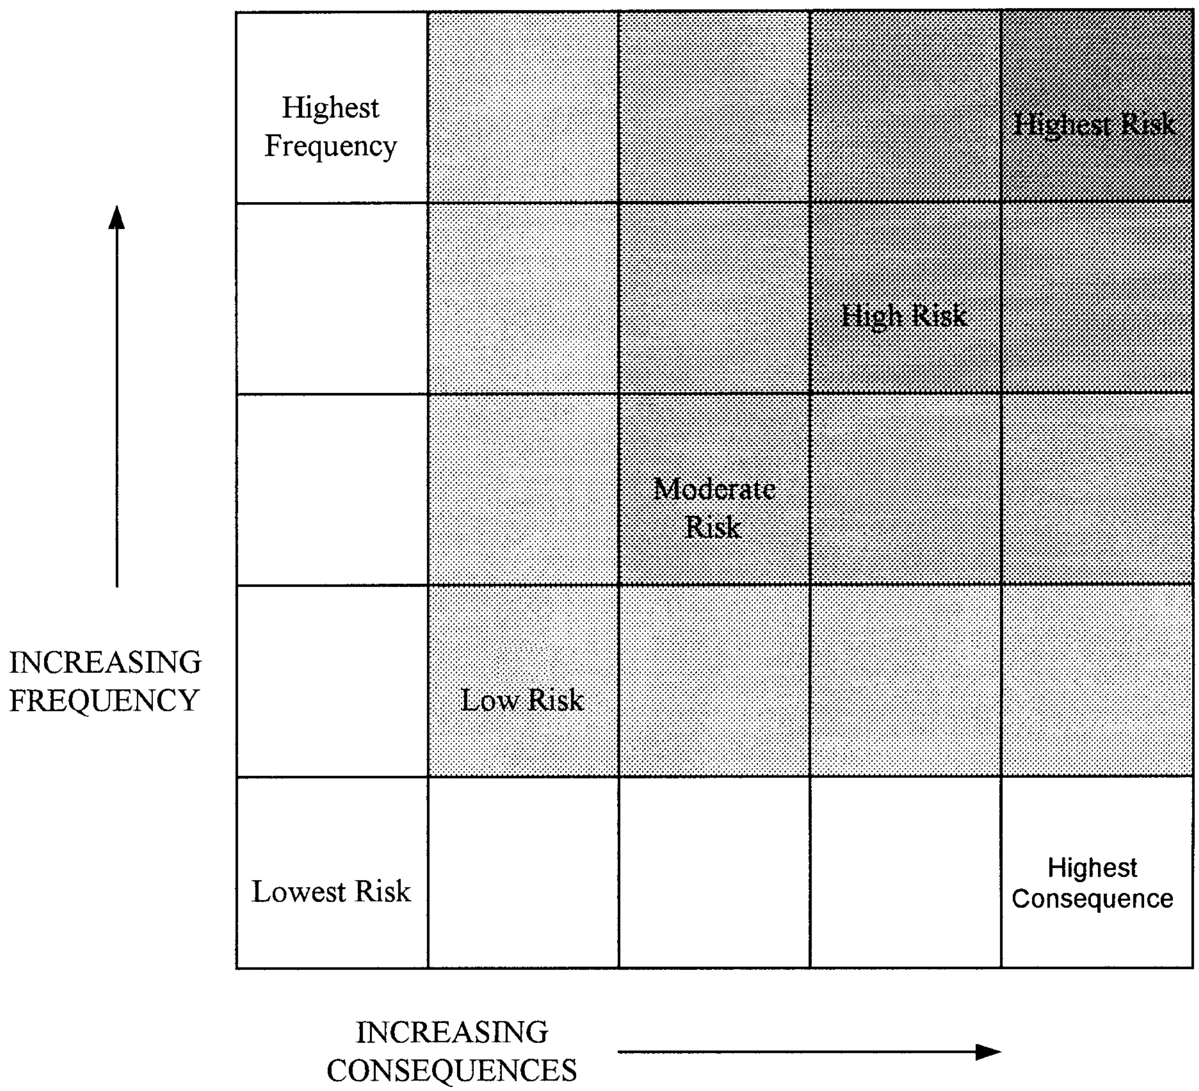

FIGURE G.1.1–1.—*Facility Accident Risk Matrix.*

G.1.2 The Meaning of Risk and Frequency as Used in this SWEIS

The word "risk" is defined in the dictionary as the probability that a specific loss or injury will occur. However, if the injury would be small, then most people would agree that the risk posed by the venture is small also. Therefore, DOE couples the consequence of an event with the probability that it will occur, and calls this combination the "risk." Note that a high-consequence event would not necessarily have significant risk (in the context of NEPA analysis) if its probability is very low.

For many events, the risk can be expressed mathematically as the product of the consequence and its probability. In illustration, if the expected public consequence of an accident at a particular facility is one cancer per accident, and if the accident has a probability of occurring once during a period of 1,000 years, then the continuing risk presented by that accident is 1 x 1/1000 or 0.001 excess latent cancer per year. This product of consequence and probability is called "societal risk" in this SWEIS. It permits the ready comparison of accidents and alternatives without the burden of the details. The details are presented in this appendix.

The probability of the accident is typically expressed as its estimated frequency; that is, an accident with a frequency of 1×10^{-3} per year has a probability of occurring once in 1,000 years and twice in 2,000 years. This is another way of saying that the probability of the accident occurring in any particular year is 1 in 1,000. In the case of natural phenomena, this is also expressed as a "return period" of 1,000 years. This does NOT mean that once the phenomenon occurs, it will be another 999 years before it occurs (returns) again, because the probability is with regard to its occurring in any selected 12-month period[1].

G.1.3 Determining the Increment in Risk Among Alternatives

Although it is possible to characterize or represent the risk posed by the operation, there are too many possibilities and uncertainties to quantify the total absolute risk. Any attempt to adjust the expected frequency and calculated consequences of risk-dominant accidents so that their sum would equal the total risk of all accidents would be self-deceptive, as all these innumerable possibilities are not independent of one another nor accurately quantifiable.

In this SWEIS analysis, it was found that the nature of the accidents did not change among the alternatives; but the frequency and consequence of some of the accidents did change somewhat. Recalling that risk is the product of the consequence and its probability, it is therefore possible to provide the decision maker with estimates of the difference in risk among the alternatives. These differences are discussed later (in summary) in Table G.5–1.

To communicate the types of risk present at LANL, the detailed methodology and results are described below. The methodology considers accidents that are reasonably foreseeable. Although "reasonably foreseeable" does not have a precise definition, the accident analysis is guided by the primary purpose of making reasonable choices among alternatives. "Reasonably foreseeable" includes impacts that may have very large or catastrophic

1. This statement is correct from a statistical standpoint but must be qualified for certain events. In the case of natural phenomena, every occurrence and every nonoccurrence adds to the database from which the probabilities are estimated, so the probabilities do change. In the case of earthquakes, an occurrence may relieve stresses and reduce the probability of another quake for some time; whereas, in the case of heavy flooding, several occurrences in a few years suggest that floods may be more likely than the original data indicated. The important point is that the frequency and/or return period are estimated measures of the probability of an occurrence, not predictions of when it will occur.

consequences, even if their frequency of occurrence is low, provided that the impact analysis is supported by credible scientific evidence, is not based on pure conjecture, and is within the rule of reason.

If an accident is not reasonably foreseeable (incredible), DOE does not consider that it contributes substantially to the risk of operating LANL (DOE 1993a). If, on the other hand, a hazardous material has a reasonable chance of being involved in an accident, then the consequences and the likelihood of the accident are considered.

Specific accidents that contribute substantially to, or envelop the risk, are considered risk-dominant accidents or bounding accidents. They are not exceeded by other accidents analyzed or believed to be possible that involve that inventory. For instance, there may be a number of accidents that could disperse plutonium, with different initiators or different mitigation; but they are represented by the risk-dominant accident involving plutonium dispersal. This accident also may bound the consequences for other facilities that may have more sensitive site characteristics, such as larger populations, but have lesser inventories than those addressed by the analyses.

There is no intent or expectation that the sum of the consequences of these accident scenarios will add quantitatively to the total risk of the LANL site. However, from the results of this methodology, the decision maker is informed of the nature and magnitude of the risk posed by operating LANL facilities.

G.1.4 The Methodology for Selection of Accidents for Analysis

The analysis began with the establishment of the baseline risk from current operations, plus planned activities, that together constitute the No Action Alternative. The baseline was established by a process of safety documentation review, interviews with facility management, physical inspections (walkdowns) of facilities, and discussions with facility management. Changes in the baseline risk were estimated for the Expanded Operations Alternative, the Reduced Operations Alternative, and the Greener Alternative to ascertain the human health impacts of the alternatives[2].

Assessing the human health consequences of accidents for the alternatives is a four-step process. The first step was to identify a broad spectrum of potential accident scenarios. These scenarios were obtained from available site-specific safety and environmental documents, programmatic documents, discussions with facility management, and physical inspections (walkdowns) of the facilities.

The second step in the process used screening techniques to identify the specific scenarios that contribute significantly to risk (i.e., the scenarios that contribute an appreciable fraction of the total risk). Due to the large number of potential accident scenarios that could impact human health, it is impractical to evaluate them all in detail. This is a common problem encountered in risk assessments, and the standard approach (which was adopted here) is to apply rough bounding calculations during the screening steps.

2. Recall, from chapter 3, that the No Action Alternative is the continuation of current operations without change in mission or the nature of operations. The Reduced Operations Alternative would be a reduction in activities to those necessary to maintain the capability in the near term. Under the Expanded Operations Alternative, operations could increase to the highest reasonably foreseeable levels over the next 10 years that can be supported by the existing infrastructure (including upgrades and construction). The Greener Alternative uses existing capabilities, but also places an emphasis on basic science, waste minimization, dismantlement of weapons, nonproliferation, and other nonweapons areas of importance, resulting in increased activities and operations in those areas of interest.

The calculations are performed to progressively greater degrees of detail until it becomes clear that the accident is either, not risk-significant, or requires a detailed analysis in order to determine the frequency and consequences of the accident (i.e., its risk).

Rigorous evaluations (the third step in the process) were only performed for the potentially risk-dominant scenarios identified in step two, that is, those which had a frequency of 10^{-6} or more and led to off-site consequences beyond insignificant.

During the third step in the process, it was determined that a number of scenarios that had appeared to be risk-significant during the earlier screening steps were in fact insignificant contributors to risk. This situation arises due to the conservative approaches to frequency binning used in safety analysis reports (SARs), as described in DOE Standard 3009-94 (DOE 1994a). DOE facilities for which SARs are prepared are subjected to the most detailed assessments; less hazardous facilities are the subject of less detailed evaluations, in accordance with the graded approach to safety analysis. For facilities with SARs, potential accidents are assigned to one of the frequency bins identified in Table G.1.4–1 (DOE 1994a). In the DOE Standard 3009-94 approach, accident frequency binning is essentially a qualitative process rather than the product of a rigorous quantitative analysis. Accordingly, frequency bin assignments are made conservatively such that if a detailed quantification were performed, the calculated frequency would not place the accident in a higher bin and would in fact be more likely to result in placement in a lower frequency bin. Sometimes, simple methods are used for frequency binning, such as assigning a conditional probability of 1 for dependent events, a conditional probability of 0.1 to human errors, and a conditional probability of 0.01 to genuinely independent events.

At the end of the detailed accident analyses, it was found that a number of accidents had been assigned to higher frequency bins than warranted. Specifically, this was the case for RAD–02, RAD–04, RAD–06, RAD–10, RAD–11, and RAD–14, all of which were found to have mean frequencies of less than 10^{-6} per year. (The sequence of events described for RAD–10 was found to be credible for worker consequences because release out of the building is not necessary to result in worker exposures.)

The fourth step in assessing the human health impact of accidents for the alternatives was to carefully evaluate the effect of the alternatives on the accident scenarios. The important considerations involved in this evaluation were whether the alternative would result in the elimination of some accidents and the addition of others, whether the alternative would result in an increase or decrease in the frequency of some accidents, and whether the alternative would result in an increase or decrease in the amount of hazardous materials released. The results of the analysis indicate that, while a number of accidents are potentially affected by the alternatives, few of them pose significant risk to the public.

In the context of LANL, it is important to recognize that, as a result of several factors (the nature of the activities performed, the design features of the facilities at which the activities are performed, the conditions under which the activities are performed, and the location of the facility vis-a-vis the public), accidents are more likely to impact facility workers than they are to impact the public. This is true even though at LANL the public has access to many areas of laboratory via roadway (public access to roads through LANL can be controlled by DOE in the event of an accident). Even for facility workers, the consequences in many cases would be dependent on the use by facility workers of personal protective equipment (PPE) and on the effectiveness of emergency response and mitigation actions taken to limit consequences (e.g., the timeliness of evacuation from the facility).

G.1.5 Comparison of Other Accident Analysis to the SWEIS

The DOE, through its safety and environmental programs, conducts a variety of hazard and safety analyses for various purposes. Because all of the safety and hazard analyses are performed for different purposes, varying levels of conservatism, and therefore, different assumptions are made about physical phenomena and preventive and mitigative controls. In the analysis, if the applicable safety objectives or standard criteria can be met with a very conservative set of assumptions, then detailed analysis is not considered necessary. Further analysis is generally done to more accurately predict an outcome when greater realism is sought, or when very conservative assumptions lead to results that exceed safety objectives or criteria. Detailed analysis requires sophisticated calculations, and therefore, greater expenditure of resources. If a very conservative estimate of consequences demonstrates that the impacts to the public, environment, and worker are acceptable within regulation or guidelines, then it is unnecessary to incur higher costs to more accurately predict the outcome. This fact may be acknowledged in the safety or hazard analysis, but no further quantification of actual doses is made. This graded approach to accident analysis is an explicit part of the DOE safety policy.

In order to understand the results of the accident analysis as presented in this SWEIS compared to other safety analyses and environmental assessments, a brief discussion of hazard assessments is given in the following sections. This discussion assumes a release of radiological material.

G.1.5.1 *DOE Hazard Assessments*

The hazard assessment is a comprehensive evaluation of hazards associated with a particular activity or operation. The hazard analysis provides a clear definition of the activity and the facilities in which the activities will be conducted. The hazard analysis identifies potential accident scenarios. From this preliminary analysis, preventative and mitigative equipment (i.e., systems, structures and components) are identified, and controls on features are established. Not every scenario is analyzed but several (often hundreds) are postulated, and those with the greatest potential for off-site consequences are usually selected as "bounding."

The hazard assessment starts with a very conservative analysis of an accident. Although activities are not conducted without the use of controls, a hypothetical baseline is established that considers only the physics of the accident, such as atmospheric dispersion, not the controls that would either prevent or mitigate the consequences. This accident may be referred to as a "parking lot scenario" or a "what-if" scenario. It is a hypothetical scenario used to gage the reduction in consequences or frequency provided by control mechanisms.

Given this estimate of a material release and considerations of atmospheric transport, the consequences are evaluated for a member of the public standing at the site boundary. This hypothetical individual receives a dose from their exposure to a passing cloud of hazardous material. The individual is assumed to remain at this location for the entire passage of the cloud or plume. These assumptions are designed to give a maximum exposure from the hazardous material release. If the dose to this individual is less than the DOE safety evaluation guideline, then the equipment associated with this activity does not need to be designated as safety class equipment. This implies that quantifying the reduction in consequences due to additional safety controls is not necessary. However, hazard assessments will often give an expected dose based on taking credit for barriers such as building high efficiency particulate air (HEPA) filters, building confinement, etc. This equipment will then have necessary controls placed on it in order to assure its operability in the event of the analyzed bounding accident.

G.1.5.2 *Accident Analysis for this SWEIS*

As described above, the hazard assessment may provide a more conservative value for the frequency of an event. This result usually reflects an estimate of the frequency of initiating events and not the overall frequency of public impacts. The final results for the SWEIS, however, included the consideration of multiple barriers; generally it considered administrative barriers, process design barriers, and facility design barriers, as appropriate. Although, the consequences of a what-if scenario were considered, they were placed in the context of their frequency of occurrence.

As a rule of thumb, most process events become "incredible." If an initiating event is considered anticipated, or has a frequency on the order of 10^{-1}, and there are three independent controls (each with an estimated probability of failure of 10^{-3}), then the overall frequency of the event becomes incredible at 10^{-10}. Therefore, once the SWEIS took credit for these barriers, the frequency of many of the accidents became less than 10^{-6}.

Several scenarios, even though they are incredible, are provided in this appendix to illustrate the defense-in-depth policy of the DOE. These accidents are retained in this appendix to preserve the information they contain, in illustration of the range of the analyses, and in demonstration of the conservative nature of the screening. Incredible accidents are not relevant to the decision and so are segregated from credible accidents in volume I of the SWEIS.

The lower frequencies are difficult to comprehend. To provide a perspective for these frequencies, some examples of natural phenomena events at LANL are provided in Table G.1.5.2–1. Estimates of large meteor impact frequencies are included in order to be able to attain the lowest frequency range.

Although specific scenarios were analyzed, the results of the detailed evaluation represent a risk profile for LANL, given the types of operations described under each alternative. As long as specific process configurations support the same type of operations as considered in these alternatives and are implemented consistent with the DOE safety program, then the risks would be represented by the same set of accidents as presented for each alternative in this SWEIS.

G.1.6 Conservatism in the Analyses

At all steps, when faced with uncertainties, the analysts selected the most probable or conservative value for accident likelihoods and the quantity of hazardous materials released. Accepted models and conservative atmospheric dispersion parameters were used in the modeling. Exposure conditions (e.g., location, material released, time in the plume) were used that would maximize exposure of the total population and of individuals. The maximum risk factor for excess latent cancer fatalities (LCFs) was used to calculate health effects; whereas, the true risk factor may be considerably less, as described in appendix D, section D.1. The resulting estimates of risks are considered to be quite conservative. Incredible accidents are not relevant to the decision and so are segregated from credible accidents in volume I of the SWEIS.

TABLE G.1.5.2–1.—*Frequency of Some Natural Phenomena Events at LANL*

DESCRIPTIVE WORDS	RANGE OF ANNUAL FREQUENCY OF OCCURRENCE	PHENOMENON AND ITS FREQUENCY
Anticipated	10^{-2} to 10^{-1}	[a]Wind of 80 mph, 10^{-2}. 11.2 inches precipitation in one month and 64.8 inches snowfall in one month[b], 1.2 x 10^{-2}.
Unlikely	10^{-4} to 10^{-2}	[a]Wind of 95 mph, 10^{-3}. [c]Snowfall adding 35.0 inches in depth in 24 hours, 5 x 10^{-3}, rainfall of 2.7 inches in 24 hours, 5 x 10^{-3}. [d]Meteor causing destructive tidal wave somewhere on earth, 2 x 10^{-4}. [e]Magnitude 6.5 earthquake causing walls to fall, houses to shift from unsecured foundation, and cracks to open in wet ground, 10^{-4}.
Extremely Unlikely	10^{-6} to 10^{-4}	[a]Straight line wind of 120 mph, 10^{-5}. Tornado with wind of 70 mph, 10^{-5}.
Incredible	< 10^{-6}	[a]Tornado with wind 150 mph or greater, 2.5 x 10^{-7}. [d]Meteor at least three miles in diameter striking somewhere on the earth, 10^{-7}.

[a] Reference for LANL wind and tornado frequency (LLNL 1985). mph = miles per hour
[b] Estimated from the record annual precipitation at LANL during November 1910 to December 1997 (*Source*: http://weather.lanl.gov)

G.2 HAZARDOUS MATERIALS IMPACTS ON HUMAN HEALTH

This section addresses the human health impacts resulting from exposure to hazardous materials. The sources of radiation pertinent to this SWEIS are examined in the first subsection. This discussion is followed by a discussion of health impacts resulting from exposure to hazardous chemicals. Finally, the computer models used to evaluate the consequences from both chemical and radiological accidents are discussed to provide an understanding of the applications and limitations of the models.

G.2.1 Sources of Radiation

The sources of radiation pertinent to the accident analysis in this SWEIS are facility specific. These sources include industrial sources used to generate x-rays and other types of electromagnetic radiation for nondestructive examination of components and assemblies. Exposure to these sources of radiation only poses a potential risk to workers and to others with authorized access to the facilities where these sources are in use. Facility-specific sources of radiation also include materials released into the environment as a result of an accident. In most cases, these materials are tritium and various mixtures of uranium and plutonium isotopes. In some cases where experiments involve pulse reactors or critical assemblies, or where criticality occurs inadvertently, fission products also can be released. Each accident scenario that involves radioactive materials includes a discussion of the isotopes and quantities considered. (The nature of radiation, and its effects on human health are discussed in section D.1 of appendix D, Human Health.)

G.2.2 Human Health Effects of Exposure to Hazardous Chemicals

Human health effects resulting from exposure to hazardous chemicals vary according to the specific chemical of interest and the exposure route and concentration. The most immediate risks to human health from exposure to chemicals in the environment arise from airborne releases of toxic gases, and it is this route of exposure upon which the accident analysis for the SWEIS is focused. (The effects of toxic chemicals are discussed in section D.1 of appendix D, Human Health.) In this analysis, exposures to toxic chemicals are compared to Emergency Response Planning Guidelines (ERPGs). ERPGs are community exposure guidelines derived by groups of experts in industrial hygiene, toxicology, and medicine. ERPGs are then published by the American Industrial Hygiene Association (AIHA) after review and approval by their ERPG Committee. ERPGs are defined as follows (AIHA 1991):

- ERPG–1 is the maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to one hour without experiencing other than mild, transient adverse health effects or perceiving a clearly defined objectionable odor.
- ERPG–2 is the maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to one hour without experiencing or developing irreversible or other serious health effects or symptoms that could impair their abilities to take protective action.
- ERPG–3 is the maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to one hour without experiencing or developing life-threatening health effects.

Human responses to chemical exposure do not occur at precise exposure levels, but rather, extend over a wide range of concentrations. The values derived for ERPGs do not protect everyone, but are applicable to most individuals in the general population. Furthermore, the ERPG values are planning guidelines, not exposure guidelines. They do not contain the safety factors normally associated with exposure guidelines (AIHA 1991).

In developing an ERPG, emphasis is given to the use of acute or short-term exposure data. Human experience data are emphasized; but usually only animal exposure data are available. When it is believed that adverse reproductive, developmental, or carcinogenic effects might be caused by a single acute exposure, the data are considered in the ERPG derivation.

Unless one is provided information to the contrary by toxicologists, it is necessary to regard ERPGs as ceiling concentrations (i.e., the highest concentration acceptable for the time period). As such, the ERPG would be treated as an exposure that should not be exceeded within 1 hour. Any extrapolation from the ERPG is not to be made without significant considerations; specifically, to make such an adjustment, the ERPG documentation for each chemical must be reviewed fully by toxicologists. The effects of exposure times longer than 1 hour may not be limited to those associated with the ERPG.

In addition to ERPGs, this analysis incorporated the temporary emergency exposure limits (TEELs) developed by the DOE Emergency Management Advisory Committee, Subcommittee of Consequence Analysis and Protective Actions (SCAPA). Published ERPG values were available for only 69 chemicals. TEEL values are interim, temporary, or ERPG-equivalent exposure limits provided for an additional 297 chemicals. In the absence of ERPG or TEEL values, the hierarchy developed by SCAPA and published in the AIHA Journal was utilized (Craig et al. 1995).

ERPG–1 defines a level that does not pose a health risk to the community but that may be noticeable due to slight odor or mild irritation. Above ERPG–2, for some members of the community there may be significant adverse health effects or symptoms that could impair an individual's ability to take protective actions. These symptoms might include severe eye or respiratory irritation or muscular weakness. Above ERPG–3 there may be life-threatening effects and, at sufficiently high concentrations and exposure times that vary with the chemical, there could be death. The length of an individual's exposure to high concentrations will depend upon that individual's situation and response (that is, by his/her recognition of the threat and its location, attaining shelter, and escaping). Later in this analysis, consequences are presented as the number of people exposed to concentration greater than the ERPG–2 and ERPG–3 guidelines; but there are too many uncertainties to speculate as to the specific effects that would occur to those people.

G.2.3 Chemical Accidents—ALOHA™ Code

The Areal Locations of Hazardous Atmospheres (ALOHA™) code developed by EPA, the National Oceanographic and Atmospheric Administration (NOAA), and the National Safety Council (NSC), was used for the analysis of chemical releases. It is listed by DOE (DOE 1994c) and EPA (EPA 1996) as an acceptable code for air dispersion modeling.

The ALOHA™ code is designed to be used for emergency responders in the case of chemical accidents. The code predicts the rate at which chemical vapors may escape to the atmosphere from broken gas pipes, leaking tanks, and evaporating puddles and predicts how the resulting hazardous gas cloud disperses horizontally and vertically into the atmosphere following release (NSC 1995).

Especially near the source of a release, short-term gas concentrations depart markedly from average values in response to random turbulent eddies and are unpredictable. As the cloud moves downwind, concentrations within the cloud become more similar to ALOHA™ calculations. ALOHA™ shows concentrations that represent averages for time periods of several minutes and predicts that average concentrations will be highest near the release point and along the center line of the release cloud (this is typical Gaussian plume modeling). The concentration is modeled as dropping off smoothly and gradually in the downwind and crosswind directions.

ALOHA™ models neutrally buoyant gases with a Gaussian plume model. Airborne particulates are assumed to be passive; that is, they behave as nonbuoyant gases. Heavy gases are modeled using a variation of the DEGADIS heavy gas model. Some simplifications were implemented into ALOHA-DEGADIS to speed computational procedures and reduce the requirement for input data that would be difficult to obtain during an accidental release. These simplifications include the assumptions that: (1) all heavy gas releases originate close to ground level; (2) mathematical approximations are faster but less accurate than those in DEGADIS; and (3) modeling sources for which the release rate changes over time as a series of short, steady releases rather than a number of individual point source puffs. The authors worked closely to ensure a faithful representation of DEGADIS model dynamics, and the resulting ALOHA-DEGADIS model was checked to ensure that only minor differences existed in results.

Although ALOHA™ models the dispersion of heavy gases, the model assumes that the terrain is flat. Thus, if canyons are located between the release point and a potential receptor, ALOHA™ models the scenario as though the canyon were not present. This is a conservative approach because receptors are offered no protection from heavy gases by intervening canyons. Under the most stable atmospheric conditions (most commonly found late at night or very early in the morning), there is little wind, reduced turbulence, and less mixing of the release with the surrounding air. High gas concentrations can build up in small valleys or depressions and remain for long periods of time. ALOHA™ does not account for buildup of gas concentrations in low-lying areas. The properties of a heavy gas are discussed in section G.5.5.

ALOHA™ allows the user to enter only a single wind speed and wind direction, and assumes that these remain constant throughout the release and travel. In reality, air flow changes speed and direction when confronted with changes in terrain such as slopes, valleys, and hills. ALOHA™ ignores these effects. Because wind is likely to shift direction and change speed over both distance and time, ALOHA™ will not make predictions for more than 1 hour after a release begins, or for distances more than 6.2 miles (10 kilometers) from the release point. In general, wind direction is least predictable when the wind speed is low and at the lowest wind speed modeled in the code (1 meter per second), ALOHA™ presents the footprint as a circle. ALOHA™ does not calculate particulate settling and deposition. The ALOHA™ code presumes the ground beneath a leak or spill to be flat, so that the liquid expands evenly in all directions.

Combustion products rise rapidly while moving downwind, until they cool to the temperature of the surrounding air. ALOHA™ does not account for this rise. ALOHA™ models the release and dispersion of pure chemicals only, and the properties of chemicals in its chemical library are valid only for pure chemicals. ALOHA™ also does not account for chemical reactions of any kind. (This limitation can be avoided by modeling the resulting chemicals, if known. In the case of the seismic collapse of TA–3–66, the SWEIS has modeled the hydrogen cyanide that evolved from mixing metal cyanide solution and nitric acid.)

The limitations of ALOHA™ do not detract from its use in this SWEIS for screening chemical accidents and bounding their daytime consequences. During the preparation of this SWEIS, as upgrades to ALOHA™ code became available they were used. Trial calculations showed that the upgrades provided the same results as previous versions for the same inputs.

G.2.4 Radiological Accidents—MACCS 2 Code

The MACCS 2 computer code models the consequences of an accident that releases a plume of radioactive materials to the atmosphere. Should such an accident occur, the radioactive aerosols and/or gases in the plume would be transported by the prevailing wind while dispersing horizontally and vertically in the atmosphere. MACCS 2 uses a straight-line Gaussian plume model and the source term data input by the user to model the atmospheric dispersion and deposition of radionuclides released from facilities. Plume rise, dry deposition, and precipitation scavenging (below cloud washout) of aerosols, and resuspension of particulate matter that has deposited from the plume is explicitly modeled. The chronic exposure model calculates the resulting doses for all inhabitants living in the area. In the intermediate and long-term phases, the inhalation shielding factor for normal activity is used in the dose calculations. Decay of radionuclides to daughter products is accounted for.

The MACCS 2 calculations also estimate the range and probability of health effects caused by radiation exposures that are not avoided by protective actions. In these EIS calculations, no credit was taken for protective measures that might and would be used to decrease exposures. (MACCS 2 permits the modeling of various protective measures, such evacuation, sheltering, and relocation. A variety of protective measures can be taken in the long-term phase in order to reduce doses to acceptable levels: decontamination, interdiction, and condemnation of property.)

MACCS 2 divides the accident into three time phases: the emergency phase, the intermediate phase, and the long-term phase. The emergency phase begins immediately after the accident and could last up to 7 days following the accident. In this period, the exposure of the population to both radioactive clouds and contaminated ground is modeled. In the intermediate phase, the radioactive clouds are gone, and decisions are made regarding the type of protective actions that need to be taken; the only exposure pathways are those resulting from ground contamination. The long-term phase represents all time subsequent to the intermediate phase, and again, the only exposure pathways considered are those resulting from the contaminated ground.

In accidents there is an initial release, and there may be a continuing release thereafter. A single MACCS 2 calculation can handle four separate releases. To account for reduction of the source as it was depleted by the continuing suspension, the continuing release was treated as three consecutive continuing releases of 8 hours each. For those accidents that have both an initial and a continuing release, the releases were stopped no later than 24 hours after the initial release.

The region surrounding the site is divided into a polar coordinate grid centered on the facility from which the release originates. The angular divisions used to define the spatial grid correspond to the 16 directions of the compass. The user specifies the number of radial divisions as well as their endpoint distances. Up to 35 of these divisions may be defined, extending out to a maximum distance of 6,213 miles (10,000 kilometers).

The emergency phase calculations use dose-response models for early fatality and early injury, and are performed on a finer grid than the calculations of the intermediate and long-term phases. For this phase, the 16 compass sectors are divided into 3, 5, or 7 user-specified subdivisions in the calculations.

Each radiological release site was assigned to the closest one of the four weather stations (located in TA–6, TA–49, TA–53, and TA–54). The 1995 meteorological data were used for these calculations. Sensitivity calculations using data from 1991 to 1995 have been performed for one accident scenario to investigate the possible impact on consequences of using weather data from a particular year. In the near field (out to 1,312 feet [400 meters]), an approximate maximum 30 percent variation occurred in the calculated doses, depending upon which year is used. The results indicated that 1995 yields the largest consequence results of this 5-year period for the scenario modeled (Steele et al. 1997).

Consequence results were calculated for both ground level and elevated releases, according to the facility and the scenario. Downwind concentrations of radionuclides up to a distance of 50 miles (80 kilometers) were calculated for each of the 16 compass directions around the facility. Radiation doses to the on-site and off-site population were calculated by the dosimetry models within MACCS 2[3], using the concentrations. Exposure pathways were: direct radiation from the passing plume, direct radiation from radioactive material deposited on the ground and skin, inhalation while within the plume, and inhalation of resuspended ground contamination. Subsequent ingestion, which normally represents only a small fraction of total exposure and can be controlled, was not considered.

3. MACCS dosimetry models use risk factors that vary by nuclide, and result in approximately, but not exactly, an effective risk factor of 5×10^{-4} excess LCFs per person-rem of exposure. This is discussed in the primer on the effects of radiation in section D.1 of appendix D, Human Health.

Because population is not evenly distributed around the source, the consequences of an accident vary with wind direction. The probability of the consequence thus depends on the probability of that wind direction. Therefore, the results of the calculations are presented as the average of the consequences for all 16 directions weighted by the probability of the wind being toward that direction. Note that the calculations used both daytime and nighttime winds; whereas, the population distribution used was the daytime population described in section G.3.2. Because the daytime population is larger than the nighttime population, this overestimates the mean consequences.

Having the results from the multiple model runs, it was possible to calculate the mean dose to hypothetical individuals at points of closest public access; at points on the site boundary (referred to as doses to maximally exposed individuals [MEIs]); and mean doses at public population centers, such as towns, pueblos, and schools.

Note that these calculations capture all meteorological conditions, including the most adverse conditions, each weighted by its frequency of occurrence in the entire year. An alternative approach, use of the dispersion condition for which dispersion is greater than 95 percent the time (referred to as 95th percentile meteorology) is often used for screening. It maximizes the concentrations downwind, but does not consider the population distribution. Therefore, it does not provide as much useful information.

Note that uncertainties as to the models' abilities to predict concentrations and exposures, and uncertainties in the range of meteorological conditions, apply equally to all the alternatives.

G.3 ACCIDENT SCENARIO SCREENING

LANL is one of the largest multiprogram research laboratories in the world, and a number of factors combined to make the selection of accident scenarios for the SWEIS a challenging task. These factors included:

- DOE NEPA guidance that mandates consideration of accidents within the design basis, as well as those beyond the design basis, to identify a spectrum of potential accident scenarios that could occur during the activities encompassed by the proposed action and analyzed alternatives.
- The diversity of activities performed at LANL, including: pit production; high explosives research, development, production, and testing; special nuclear material (SNM) processing, research and development, and storage; hydrodynamic testing and dynamic experimentation; accelerator operations, research, and development; fusion power research and development; operation critical assemblies and fast burst reactors; and radioactive, chemical, and mixed waste processing, characterization, disposal, and storage.
- A wide range of accident initiators (including process hazards, man-made hazards, and natural phenomena hazards) and the resulting human, system, and structural responses to those initiators.
- A large number of accident scenarios identified in underlying programmatic and LANL-specific NEPA documents (e.g., the Stockpile Stewardship and Management PEIS, and the Dual Axis Radiographic Hydrodynamic Test [DARHT] Facility EIS).
- The availability and vintage of a variety of hazard assessment and safety analysis documentation, performed to evolving DOE guidance.

- The diversity of material that could potentially be released in an accident (referred to as "material-at-risk" or MAR), including: tritium, plutonium, various enrichments of uranium, toxic chemicals such as chlorine, bulk acid storage, high explosives, and a wide variety of other chemicals and radioactive materials.
- The presence of some relatively complex facilities such as the Plutonium Facility (TA–55–4), the Chemistry and Metallurgy Research (CMR) Building (TA–3–29), the Tritium System Test Assembly (TSTA) Facility (TA–21–155), the Tritium Science and Fabrication Facility (TSFF, TA–21–209), the Weapons Engineering Tritium Facility (WETF, TA–16–205), and the critical assembly and fast burst reactor facilities at the Pajarito site (TA–18), for which hazard and safety analyses have identified dozens to hundreds of credible accident scenarios for each of these facilities.

The large number of facilities and processes at LANL, combined with the diversity of MAR and the variety of accident initiators, produce credible accident scenarios numbering at least in the many thousands. Analyzing each of these scenarios in detail is neither required under NEPA nor practical. Ideally, a comprehensive risk assessment would express the total human health risk as the sum of all potential accident scenarios. It is neither practical (due to cost) or necessary (from a NEPA compliance standpoint) to rigorously quantify all of these to produce a summation of the total risk. The purpose of screening is to identify for detailed analysis a suite of accidents that constitute a large fraction of the total risk.

Accident analyses, for a NEPA document, involve considerably less detail than a formal probabilistic risk assessment (PRA), but make use of PRA techniques and insights (such as event trees, failure rate data, and initiating event occurrence data) to identify risk-significant accident scenarios.

G.3.1 Accident Initiator Screening

It was recognized, based on review of available safety documentation for several important facilities, that there would be a very large number of credible accident scenarios for LANL facilities. The SWEIS accident analysis began with a detailed examination and screening of accident initiators and accident types in order to focus the attention of the remainder of the analysis on those accident initiators most important to risk. Accident initiators and accident types were identified and categorized into three broad classes: (1) process hazards, (2) man-made hazards, and (3) natural phenomena hazards (NPHs). Military action, sabotage, terrorism, or other forms of deliberately malevolent actions were not included. The magnitudes of the likelihood and consequences of such acts are independent of the site operations, under the purview of security and protection forces, and are considered to be outside the purview of accident analysis.

The list of accident types and initiators, arrayed into these three categories, is provided as Table G.3.1–1. These accident types and initiators were evaluated in the context of their likelihood and their potential for resulting in a release of hazardous materials or for causing an event that could result in such a release (e.g., a fire or explosion). Hazardous materials at LANL include radioactive materials, chemicals, biohazards, and high explosives.

The intent is to capture all accidents that have a frequency in excess of 1×10^{-6} per year. It is not possible to estimate accurately the likelihood (frequency) of accidents with very low probability. Therefore, accident types and accident initiators that could produce an accident with a frequency in excess of 1×10^{-7} per year when realistically estimated, or a frequency in excess of 1 x 10^{-6} per year when conservatively estimated, were treated as “credible” and “reasonably foreseeable.”

Accidents with frequencies less than 1 x 10^{-6} were not dismissed without considering whether they were capable of producing worse consequences than credible accidents. Large earthquakes would affect the entire LANL site simultaneously. As a result, it is not considered plausible that many individual but unlikely accidents could rival earthquakes in overall risk, and thus, were not retained for detailed analysis.

A suite of accident type and accident initiator screening criteria was developed for the purpose of evaluating the master event list in Table G.3.1–1. It is important to recognize that, while some of the accident types or initiating events listed in Table G.3.1–1 may appear to some readers to stray into the realm of the absurd, the goal of the master listing and the screening process was to demonstrate that the consideration of accident types and accident initiators was as comprehensive as possible.

The accident types and initiators in the master list were screened, using the screening criteria in Table G.3.1–2. Results of the screening for process hazards, man-made hazards, and natural phenomena hazards are reported separately in Tables G.3.1–3, G.3.1–4, and G.3.1–5, respectively.

Table G.3.1–6 summarizes the three preceding tables as events the survived that screening. These were subsequently evaluated on a facility-specific basis, using detailed safety documentation review and facility walkdowns, as described in the following section G.3.2.

G.3.2 Facility Hazard Screening

DOE assigns different hazard categories to its facilities on the basis of the magnitude of maximum potential injuries and fatalities on site and off site. Although the system has a different purpose than identification of facilities to be considered in EIS analyses, the past categorization constituted an effective screening of facilities for this SWEIS.

In hazard classification, no credit is given designed active safety features[4], administrative controls (other than those limiting the total quantity of hazardous materials in the facility), or prompt emergency response. Credit for mitigation is assumed only for substantial passive primary barriers or natural removal or dispersal mechanisms associated with the distance between the facility and the receptor location (LANL 1995a). Hazard classification is therefore considered to represent an appropriate basis for an initial screening of LANL facilities to focus the attention of the SWEIS accident analysis on those facilities that have the most significant potential for causing impacts to workers, the public, and the environment.

This screening step is based on the hazard posed by the facility. There may be other reasons for including facilities in the accident analysis (e.g., stakeholder interest). Such additional facilities were selected by expert judgment. The facilities that were identified in the initial hazard categorization process are listed in Table G.3.2–1. Following detailed discussions with LANL, walkdowns of more than 40 facilities, and review of updated safety documentation, many of the facilities in Table G.3.2–1 were screened from further analysis. Table G.3.2–2 provides a listing of the facilities that were screened and a summary of the reasons for their exclusion from detailed analysis. Table G.3.2–3 provides the final list of facilities that were subjected to screening consequence analysis in

4. An “active safety feature” is one that is fallible, through its dependence upon maintenance, electrical power, human operation, etc. Examples would be a smoke alarm, filtering system or automatic electrical switch. A “passive” feature or barrier is one that does not require dependable human attention for its operation. Examples are a berm, catch basin, or firewall.

TABLE G.3.1–1.—*Accident Type and Initiating Event Master Classification List*

PROCESS HAZARDS	MAN-MADE HAZARDS	NATURAL PHENOMENA HAZARDS	NATURAL PHENOMENA HAZARDS (CONT.)
Biohazard Spill	Aircraft Crash[h]	Avalanche	Lightning Strike[bb]
Chemical Spill[a]	Arson	Barometric Pressure[s]	Liquefaction[cc]
Container Failure	Co-Located Facilities[i]	Biological Hazards[t]	Low Water Level
Criticality Event[b]	Dam Failure[j]	Blizzards[u]	Nontectonic Deformation
Explosion[c]	Dike Failure[j]	Climatic Change[v]	Precipitation Extremes
Fire[d]	Explosion[k]	Coastal Erosion	River Diversion
Flooding[e]	Fire[l]	Drought	Sand Storms
Hardware Failure[f]	Flooding[j]	Dust Storms	Seiche
Human Error[g]	Levee Failure[j]	Earthquakes[w]	Sink Holes and Collapse
Radioactive Spill	Military Action[m]	Extraterrestrial Objects[x]	Slope Stability
	Nuclear Detonation[n]	Fog	Snow
	Pipeline Failure[o]	Frost	Soil Consolidation
	Sabotage and Terrorism[p]	Glacial Activity[y]	Soil Shrink/Swell
	Satellite Orbital Decay	Hail	Storm Surge
	Shipwrecks	High Water[j]	Temperature Extremes[dd]
	Vandalism[q]	High Wind[z]	Tornadoes[ee]
	Transportation[r]	Hurricanes	Tsunami
		Ice and Ice Jams	Volcanism[ff]
		Landslides and Mudflows[aa]	Waves

Notes:

[a] Includes release of chemicals, including toxic gases, liquids, solids, high explosives, etc. that disperse into the facility or environment. Also includes uncontrolled chemical reactions due to inadvertent mixing of chemicals (e.g., mixing of metal cyanide solution and acid, which liberates hydrogen cyanide).

[b] Represents all accidental or unplanned nuclear criticality events, including criticality in solid systems, aqueous solutions, and waste forms. Does not include planned criticality during critical assembly experiments or fast burst reactor operations.

[c] Represents explosions due to sources of explosive materials (gases, etc.) originating within the facility. Does not include ingestion of explosive gases into the heating, ventilation, and air conditioning (HVAC) system from outside the facility. Explosions may be accompanied by a fire.

[d] Represents fires originating within a facility.

[e] Represents flooding originating within a facility (due, for example, to a pipe break or an inadvertent actuation of a fire sprinkler system).

[f] Includes hardware failures due to any cause (such as aging, overheating, overcooling, lubrication system failure, etc.) except military action, sabotage, terrorism, or other forms of deliberately malevolent actions.

[g] Includes human errors in any phase of design, construction, fabrication, operation, maintenance, modification, design control, management, emergency response, etc.

[h] Includes direct impact on the facility as well as a crash near the facility followed by the skidding of the aircraft or aircraft components into the facility. Also includes fires or explosions resulting from aircraft crash (due to combustion of aviation fuel and/or the contents of the aircraft), as well as impacts of missiles on the facility resulting from the aircraft crash or resulting fire/explosion.

[i] Represents accidents at nearby facilities (off-site industrial facilities, other on-site facilities, military facilities, etc.) that cause an impact at the facility under evaluation. Such accidents would include explosions, fires, chemical accidents, toxic gas releases, etc.).

TABLE G.3.1–1.—*Accident Type and Initiating Event Master Classification List*-Continued

[j] Includes failures due to human errors (such as design errors, failure to anticipate sufficiently severe flood and debris conditions, construction errors, etc.).
[k] Includes explosions from sources outside the facility, but does not include explosions due to pipeline accidents, sabotage, or military action.
[l] Includes fires from sources outside the facility, such as wildfires.
[m] Includes acts of war, as distinguished from sabotage, terrorism, arson, etc. Also includes war-like actions during internecine conflicts.
[n] Includes only the inadvertent detonation of a nuclear explosive device. No nuclear weapons or nuclear explosive devices will be assembled, disassembled, or otherwise handled at LANL under any of the alternatives.
[o] Includes accidents involving natural gas pipelines that can result in fires and/or explosions.
[p] Includes acts committed by authorized insiders (persons with authorized access to the facility) or outsiders (including visitors) that are committed with the intent of causing a release of radioactive materials, hazardous chemicals, high explosives, or biohazards or that are committed with the intent of causing a nuclear criticality event. The acts could take place at the facility or outside the facility (e.g., destruction of a dam, deliberate crash of an aircraft, etc.).
[q] Includes acts committed by authorized insiders or outsiders (including visitors) that are not intended to cause a release of radioactive materials, hazardous chemicals, high explosives, or biohazards or that are not intended to cause a criticality, but that nonetheless result in such occurrences contrary to the intent of the perpetrators.
[r] Includes accidents resulting in release of radioactive materials, hazardous chemicals, high explosives, or biohazards, or that result in a nuclear criticality event, occurring in all modes of transportation (truck, car, rail, aircraft, or ship) that involve material being shipped to or from the facility. Also includes impact of a vehicle from all modes of transportation (except aircraft, which is analyzed separately in this appendix) on the facility that causes damage to the facility (but that may or may not be transporting hazardous cargo).
[s] Includes normal changes in barometric pressure. Does not include changes in air pressure due to the passage of a tornado, which is analyzed separately.
[t] Includes accidents caused by biological factors such as ingestion of plant debris by cooling systems, blockage of cooling systems by mussel and clam infestations, excessive biological growth on the exterior of facility structures, etc. Does not include fire involving plants (wildfire), which is analyzed separately.
[u] Includes effects from excessive loads due to snow accumulation on or against facility structures.
[v] Includes such effects as global warming (and its impacts), glaciation (and its impacts), and other impacts of changes in weather that are not within the range of normally expected conditions. Does not include impacts due to existing glaciers.
[w] Includes effects such as seismically initiated liquefaction, dam failures, fires, and flooding, as well as surface deformation, tectonic subsidence, tectonic uplift, and damage due to ground accelerations (vertical and horizontal).
[x] Includes direct impact on the facility of meteorites, comets, asteroids, and other extraterrestrial bodies, as well as collateral damage resulting from impacts elsewhere (surface deformation, missile impacts, flooding, etc.).
[y] Includes impacts due to glaciers existing at the time of the analysis. Such impacts include the effects of both the advance and retreat of glaciers.
[z] Includes straight winds, as distinguished from hurricanes and tornadoes, and also includes wind-borne missiles.
[aa] Does not include landslides and mud flows due to volcanic activity.
[bb] Includes the impacts of fires caused by lightning strikes. For structures with lightning protection, this requires consideration of possible failures of lightning protection systems.
[cc] Does not include seismically initiated liquefaction, which is included under earthquakes.
[dd] Includes effects of freezing of equipment due to low external temperatures.
[ee] Includes impacts due to tornado-borne missiles, differential pressure due to nearby tornado passage, and lightning strikes, hail, rain, and other phenomena due to storms associated with the tornado weather system.
[ff] Includes such effects as ash falls, rock falls, nueé ardente, rapid snow-pack-melt-induced flooding, mud flows, siltation, sedimentation, phreatomagmatism, pyroclastic activity, etc. and fire/explosion.

TABLE G.3.1–2.—*Accident Type and Accident Initiator Screening Criteria*

SCREENING CRITERION	SCREENING CRITERION DESCRIPTION
1	The accident type or initiating event is within the facility design basis, and the frequency in combination with the conditional probability of a sufficiently severe design error affecting parameters that would cause failure of the facility is considered to be incredible (i.e., frequency less than 1 x 10^{-6} per year (conservatively evaluated); or
2	The initiating event does not occur close enough to the facility to affect it (this is a function of the magnitude of the event and the proximity of the facility to the event); or
3	The accident type or initiating event is included in the definition of another event due to the similarity of impacts on the facility, and the frequency contribution of the other event includes the contribution from this event; or
4	The event has a sufficiently cataclysmic impact on the facility as well as on the surrounding region such that the consequences of the event on the surrounding region would not be significantly affected by the destruction of the facility; or
5	The accident type or initiating event has a conservatively estimated mean frequency of less than 1 x 10^{-6} or a realistically estimated mean frequency of less than 1 x 10^{-7} per year; or
6	The accident type or initiating event is under the purview of the security and protection forces and the security and safeguards related administrative and physical controls, and is the result of deliberate act; these events are considered to be outside the purview of an “accident” analysis, which is concerned with unanticipated events that occur at random.

TABLE G.3.1–3.—*Process Hazards Screening Results*

ACCIDENT TYPE OR INITIATING EVENT	SCREENING CRITERIA						SCREENS OUT (Y/N)	NOTES
	1	2	3	4	5	6		
Biohazard Spill							No	Applicable to workers only; no credible scenario for spread of biohazard beyond the LANL workforce
Chemical Spill							No	Chemical spill hazards bounded by toxic gases and liquids that are easily dispersed
Container Failure			X				Yes	Contributing event to chemical spill and radioactive spill
Criticality Event							No	Applicable to workers only; public dose consequences of criticality event are less than 100 millirem
Explosion							No	
Fire							No	
Flooding	X		X				Yes	Possible contributing cause for criticality events; criticality retained
Hardware Failure			X				Yes	Embedded in other events as contributory causes; also represented as causes of system failures after an initiating event
Human Error			X				Yes	Embedded in other events as contributory causes; also represented as causes of system failures after an initiating event
Radioactive Spill							No	

TABLE G.3.1–4.—*Man-Made Hazards Screening Results*

ACCIDENT TYPE OR INITIATING EVENT	SCREENING CRITERIA						SCREENS OUT (Y/N)	NOTES
	1	2	3	4	5	6		
Aircraft Crash							No	Analysis to be performed per DOE Standard 3014-96 (DOE 1996c)
Arson						X	Yes	Malevolent act
Co-Located Facilities							No	
Dam Failure		X			X		Yes	
Dike Failure		X			X		Yes	
Explosion							No	
Fire							No	
Flooding							No	TA–18 only; other hazardous facilities located on mesa tops
Levee Failure		X			X		Yes	
Military Action						X	Yes	Malevolent act
Nuclear Detonation					X	X	Yes	No nuclear weapons or nuclear explosive devices are assembled, disassembled, handled, or otherwise processed at LANL
Pipeline Failure							No	TA–3–29 only
Sabotage and Terrorism						X	Yes	Malevolent acts
Satellite Orbital Decay					X		Yes	
Shipwrecks		X			X		Yes	
Transportation							No	Transportation analysis performed separately from accident analysis
Vandalism						X	Yes	Malevolent acts

TABLE G.3.1–6.—*Credible Accident Types and Accident Initiators that Survived Early Screening*

PROCESS HAZARDS
Biohazard Spill
Chemical Spill
Criticality Event[a]
Explosion (Internal to Facility)
Fire (Internal to Facility)
Radioactive Spill
MAN-MADE HAZARDS
Aircraft Crash—analyzed based on DOE Standard 3014–96 (DOE 1996c)
Co-Located Facilities[b]
Explosion (External to Facility)[b]
Fire (External to Facility)
Flood (External to Facility)—TA–18 only[b]
Pipeline Failure—TA–3–29 only; other facilities screened
Transportation Accidents—analyzed separately from facility accidents
NATURAL PHENOMENA HAZARDS
Earthquakes
High Wind[b]
Lightning Strike[b]
Slope Stability—TA–18 only[b]
Volcanism[c]

[a] Screened out for public risk based on low dose; retained as a worker accident.
[b] Later screened out, based on subsequent facility- and site-specific review.
[c] Credible, but not used, based on higher level of risk posed by earthquakes.

order to select the final suite of facilities for detailed analysis.

G.3.2.1 *Description of the DOE Hazard Category System*

As background information only, this subsection describes the hazard categorization system used by DOE.

Facilities performing radiological operations are subdivided into hazard categories pursuant to DOE Order 5480.23 and DOE Standard 1027-92 (DOE 1992). There are three hazard categories based on the type of facility (Hazard Category 1) or the radiological inventory (Hazard Categories 2 and 3). These facilities are defined as nuclear facilities. Facilities that do not meet the threshold requirements for Hazard Category 3 but that still contain radioactive materials are categorized as radiological facilities.

The three hazard categories for these facilities are defined as follows (DOE 1992):

- *Hazard Category 1.* Hazard analysis shows the potential for significant off-site consequences (limited to Category A reactors and other facilities designated by the Program Secretarial Officer). (Note: There are no facilities at LANL designated by LANL or DOE as Hazard Category 1).
- *Hazard Category 2.* Hazard analysis shows the potential for significant on-site consequences (includes facilities with the potential for nuclear criticality events or with sufficient quantities of hazardous materials and energy that would require on-site emergency planning activities). Threshold quantities of radionuclides for Hazard Category 2 facilities are shown in Appendix A of DOE Standard 1027-92 (DOE 1992), with LANL-specific elaboration provided in a separate document (LANL 1995b).
- *Hazard Category 3.* Hazard analysis shows the potential for only significant localized consequences. Threshold quantities of radionuclides for Hazard Category 3 facilities are shown in Appendix A of DOE Standard 1027-92, with LANL-specific elaboration provided in a separate document (LANL 1994a).
- *Radiological Facilities.* Facilities not meeting at least Hazard Category 3 threshold criteria but that still possess some amount of radioactive materials. No other hazard identified than normal office or laboratory environment (electrical equipment, glassware, tools, etc.).

TABLE G.3.2–1.—*LANL Facilities Identified in Initial Hazard Categorization*

HAZARD CATEGORY 2 NUCLEAR FACILITIES	HAZARD CATEGORY 3 NUCLEAR FACILITIES	MODERATE HAZARD CHEMICAL FACILITIES	LOW HAZARD CHEMICAL FACILITIES	FACILITIES SELECTED BASED ON JUDGMENT
TA–2–1, Omega West Reactor	TA–3–66, Sigma Facility	TA–00–1109, Chlorinator	TA–3–39, Shops Building	TA–3–30, General Warehouse
TA–3–29, Chemistry & Metallurgy Research Building	TA–3–159, Sigma Thorium Storage Facility	TA–00–1110, Chlorinator	TA–3–141, Beryllium Technology Building	TA–3–35, Press Building
Dynamic experiment activities involving Special Nuclear Materials[a]	TA–18–23, Pajarito Site Kiva #1	TA–00–1113, Chlorinator	TA–3–1698, Materials Science Laboratory	TA–3–102, Shops Building
TA–16–205 Weapons Engineering Tritium Facility	TA–18–26, Pajarito Site Hillside Vault	TA–00–1114, Chlorinator	TA–21–5, Chemistry Building	TA–3–164, Uranium Storage Building
TA–18–32, Pajarito Site Kiva #2	TA–18–116, Pajarito Site Kiva #3	TA–3–31, Chemical Warehouse	TA–21–150, Molecular Chemistry Building	TA–3–166, Wastewater Treatment Plant
TA–21–155, Tritium Systems Test Assembly	TA–18–168, Pajarito Site Solution High-Energy Burst Assembly (SHEBA)	TA–3–170, Gas Plant	TA–43–1, Health Research Laboratory	TA–9–21, Analytical Chemistry Building
TA–21–209, Tritium Science and Fabrication Facility	TA–21–146, Filter Building	TA–3–476, Toxic Gas Storage Shed	TA–59–1, Occupational Health	TA–9–23, Shops Building
TA–50–37, Radioactive Materials Research, Operations, and Demonstration Facility	TA–35–2, Laboratory	TA–14–5, Toxic Gas Storage	TA–54–39, polychlorinated biphenyl (PCB) Waste Storage	TA–11–30, Vibration Test
TA–54–229, TA–54–230, TA–54–231, and TA–54–232, Transuranic Waste Inspectable Storage Project	TA–35–27, Nuclear Safeguards Laboratory	TA–16–560, Chlorinator	TA–60–29, Pesticide Storage	TA–15–184, Pulsed High-Energy Radiation Machine Emitting X-Ray (PHERMEX)
TA–54–48, TA–54–153, TA–54–224, TA–54–226, and TA–54–286, Transuranic Waste Storage Domes	TA–48–1, Radiochemistry Facility	TA–21–3, Chemistry Building		TA–16–260, High Explosives Processing (Example)

HAZARD CATEGORY 2 NUCLEAR FACILITIES	HAZARD CATEGORY 3 NUCLEAR FACILITIES	MODERATE HAZARD CHEMICAL FACILITIES	LOW HAZARD CHEMICAL FACILITIES	FACILITIES SELECTED BASED ON JUDGMENT
TA–55–41, Nuclear Materials Storage	TA–50–69, Waste Characterization, Reduction, and Repackaging Facility	TA–35–213, Target Fabrication Facility		TA–16–340, High Explosives Pressing (Example)
	Isotope production activities and radiation effects experiments at the Los Alamos Neutron Science Center (LANSCE)[b]	TA–46–340, Wastewater Treatment Facility Chlorination Building		TA–41–1, Ice House
	TA–54–38, Radioassay and Nondestructive Testing Facility	TA–54–216, Legacy Toxic Gas Storage		TA–46–154, Applied Photochemistry
	TA–55–185, Transuranic (TRU) Drum Staging Facility	TA–54–1008, Chlorinator		
		TA–72–3, Chlorinator		
		TA–73–9, Chlorinator		

[a] Activities utilize or occur at several host facilities at which special nuclear material associated with Hazard Category 2 may reside for short durations. These host facilities include TA–8–23 (Radiography), TA–16–411 (Assembly Building), and TA–15 (PHERMEX), and the DARHT facility when it is completed.

[b] LANSCE, TA–53, is a nonnuclear facility that hosts several activities typically of limited duration that are considered to be Hazard Category 3, including isotope production and experiments using small quantities of actinides. The risks associated with these occasional, short duration activities involving these materials at these facilities have been evaluated in DOE safety analyses and controls are in place while the material is in the facilities.

TABLE G.3.2–2.—*LANL Facilities Screened from Analysis, with Screening Rationale*

FACILITY	FACILITY NAME AND SCREENING RATIONALE
TA–0–1113	Potable Water Chlorinator—Located in canyon; chlorine is a heavy gas that in high concentrations will proceed down the canyon, away from populated areas; no unique worker accidents; no biohazards; no radioactive materials.
TA–0–1114	See TA–0–1113.
TA–2–1	Omega West Reactor—Not scheduled for operation in a SWEIS alternative. All nuclear material has been moved from this facility, and the facility has been removed from the site's nuclear facility list.
TA–3–30	General Warehouse—No radioactivity or biohazards; chemical inventory screened; no unique worker hazards.
TA–3–31	Chemical Warehouse—No radioactivity or biohazards; chemical inventory screened; no unique worker hazards.
TA–3–35	Press Building—Radiological facility only; radiological hazards bounded by other nearby facilities. No chemicals or biohazards. No unique worker hazards.
TA–3–39	Shops Building—No unique worker hazards; no biohazards. Impacts from depleted uranium or beryllium bounded by other facilities (TA–3–66, TA–3–141).
TA–3–102	See TA–3–39.
TA–3–141	Beryllium Technology Building—No credible public accidents. No biohazards; no radioactivity.
TA–3–142	Shipping and Receiving Warehouse—Transient radioactivity only (less than Hazard Category 3 quantities). Chemical inventory screened (ERPG–3 < 100 meters). No biohazards. No unique worker hazards.
TA–3–159	Sigma Thorium Storage Facility—Facility contains only thorium; consequences bounded by other facilities; passive storage only, nonpyrophoric forms, low combustible loading.
TA–3–164	Uranium Storage Facility—Inventory removed. No use projected for any SWEIS alternative.
TA–3–166	Wastewater Treatment Plant—Chlorine inventory removed; facility no longer treats wastewater. No biohazards or radioactivity. No unique worker hazards.
TA–3–170	Compressed Gas Processing Facility—No radioactivity or biohazards. No unique worker hazards. Chemical inventory screened (ERPG–3 <100 meters).
TA–3–1698	Materials Science Laboratory (MSL)—No credible accidents; radioactivity and chemical inventories screen. No unique worker hazards; no biohazards.
TA–8–22	Radiography—Facility performs radiography of (among other things) pits and DARHT assemblies. Low combustible loading and similar seismic resistance to other facilities at which these materials will be present for a much greater percentage of the time. The risks of accidents at TA–8–22 are bounded by the risks of accidents at the other facilities. No unique worker accidents (radiography performed at other facilities as well).
TA–8–23	See TA–8–22.
TA–9–23	Shops Building—Radiological inventory below Hazard Category 3; chemical inventory screens (ERPG–3 <100 meters). No biohazards. No unique worker hazards. Remote location.

TABLE G.3.2–2.—*LANL Facilities Screened from Analysis, with Screening Rationale*-Continued

FACILITY	FACILITY NAME AND SCREENING RATIONALE
TA–9–30	Nuclear Material Storage—Maximum radiological inventory is 100 kilograms of depleted uranium and less than 0.1 grams of tritium (less than Hazard Category 3). Chemical inventory screens (ERPG–3 < 100 meters). No biohazards. No unique worker hazards. Remote location; depleted uranium accident consequences bounded by other facilities with greater inventory and in more densely populated area.
TA–11–30	Vibration Test Building—Transient radiological inventory only (same materials present at other facilities in greater quantity and/or more frequently). No chemicals or biohazards. No unique worker hazards.
TA–14–5	Toxic Gas Storage Building—Inventory removed. No use projected for any SWEIS alternative.
TA–15–184	PHERMEX—Firing site with no unique hazards (any hazards at PHERMEX bounded by those at DARHT and other facilities). No unique worker hazards. No biohazards. More remote than other facilities with similar MAR.
TA–16–260	High Explosives Processing—No radioactivity or biohazards. No unique worker hazards. Detonation hazards limited to workers due to exclusion area and blowout panels.
TA–16–305	High Explosives Chemical Storage—No radioactivity or biohazards. No unique worker hazards. Chemical inventory screens (ERPG–3 < 100 meters). Contained in former high explosives magazine.
TA–16–340	High Explosives Pressing Facility—No radioactivity or biohazards. No unique worker hazards. Detonation hazards limited to workers due to exclusion area and blowout panels.
TA–16–410	Assembly Facility—Activities at TA–16–410 are comparable to those at TA–16–411, and the MAR at TA–16–410 is bounded in hazard and quantity by MAR at TA–16–411.
TA–16–560	Potable Water Chlorinator—Consequences limited to area containing few buildings. No public consequences (except possibly a limited number of commuters on West Jemez Road). No unique worker hazards; no biohazards; no radioactivity. Impacts bounded by other potable water chlorinators.
TA–18–26	Pajarito Site Hillside Vault—Passive vault storage of plutonium and highly enriched uranium (HEU) in a vault built into the side of a mesa. Very low combustible loading, no active HVAC systems. Infrequent access. Seismic collapse would bury MAR with no significant release to the environment. No credible accidents; very low frequency accidents bounded by those at other storage facilities (TA–3–29, TA–55–4).
TA–21–3	Chemistry Building—Facility undergoing decontamination and decommissioning; completion scheduled prior to final SWEIS issuance.
TA–21–4	See TA–21–3.
TA–21–5	See TA–21–3.
TA–21–146	Filter Building—Filter building for former plutonium activities at TA–21. Decontamination and decommissioning will be completed prior to final SWEIS issuance.
TA–21–150	See TA–21–3.
TA–35–2	Laboratory—The only MAR is radioactive sources, which screen under DOE Standard 1027-92 (DOE 1992).
TA–35–27	Nuclear Safeguards Laboratory—The only MAR is radioactive sources, which screen under DOE Standard 1027-92.

TABLE G.3.2–2.—*LANL Facilities Screened from Analysis, with Screening Rationale*-Continued

FACILITY	FACILITY NAME AND SCREENING RATIONALE
TA–35–213	Target Fabrication Facility—No radioactive materials (except less than Hazard Category 3 quantities of depleted uranium and tritium). No biohazards. Some toxic chemicals present, but located in fume hoods with active ventilation. Under seismic collapse conditions, toxic effects remain within TA (facility adjacent to canyon, which will preclude transport of high concentrations of heavy gases); workers would be impacted by the seismic collapse in any event.
TA–41–1	Ice House—Former radiological inventory removed (residual contamination only). No storage or processing in any SWEIS alternative. No chemicals or biohazards. No unique worker hazards.
TA–46–154	Applied Photochemistry—No radioactivity or biohazards. No unique worker hazards. Chemical inventory screens (ERPG–3 < 100 meters).
TA–48–1	Radiochemistry Facility—All MAR (radioactive and chemical) screen (i.e., radioactivity less than Hazard Category 3, except for hot cells; chemicals screen at ERPG–3 at less than 100 meters). Any impacts would be limited to the TA–48 site area.
TA–53	LANSCE and Manuel Lujan Neutron Scattering Center (MLNSC)—No credible accidents. No unique worker accidents. No biohazards.
TA–54–33	Drum Preparation Facility—No chemicals or biohazards. No unique worker hazards. MAR limited and bounded by other nearby facilities (TA–54–38, TA–54–G Transuranic Waste Inspectable Storage Project [TWISP]).
TA–54–49	Low-level Mixed Waste Storage Dome—No biohazards. No unique worker hazards. Radiological hazards bounded by other nearby facilities with much larger inventories (TA–54–G, TWISP).
TA–54–1008	Potable Water Chlorinator—No receptors within ERPG–2 distance. No unique worker hazards; no biohazards or radioactivity.
TA–55–5	Plutonium Facility Warehouse—Chemical inventory removed; staging area only with transitory chemical inventory. No changes expected for any SWEIS alternative. Bounded by TA–55–4 chemical accidents (e.g., chlorine, hydrogen fluoride gas, nitric acid, hydrochloric acid).
TA–55–41	Nuclear Materials Storage Facility (NMSF)—Storage activities at TA–55–41 mirror those at TA–55–4. No unique hazards at TA–55–41. TA–55–41 connected to TA–55–4 via an underground tunnel. Risks at TA–55–41 bounded by those at TA–55–4.
TA–60–29	Pesticide Storage Building—Passive storage facility; chemicals screen or are bounded by the effects of chemical releases at other nearby facilities. No biohazards or radioactivity.
TA–72–3	Potable Water Chlorinator—No receptors within ERPG–2 distance. No unique worker hazards; no biohazards or radioactivity.
TA–73–1	Los Alamos Airport—Covered under transportation accident analysis. Aircraft crash associated with missed landings, etc., covered in facility aircraft crash accident analysis (DOE Standard 3014-96, DOE 1996b).
TA–73–9	Potable Water Chlorinator—Located on steep hill. Chlorine is a heavy gas that in high concentrations will proceed downhill into a canyon. Any impacts to commuters on State Road 502 will be bounded by chlorine release from other potable water chlorinators (TA–0–1109, TA–0–1110).

TABLE G.3.2–3.—*Final List of LANL Facilities to be Subjected to Screening Consequence Analysis*

TECHNICAL AREA AND BUILDING NUMBER	FACILITY NAME
TA–0–1109	Potable Water Chlorinator
TA–0–1110	Potable Water Chlorinator
TA–3–29	CMR Building
TA–3–66	Sigma Facility
TA–3–476	Toxic Gas Storage Shed
TA–9–21	Analytical Chemistry Building (worker hazard only)
TA–15–312	DARHT Facility
TA–16–205	WETF
TA–16–411	Assembly Building
TA–18–23	Pajarito Site Kiva #1 (seismic and aircraft crash only)
TA–18–32	Pajarito Site Kiva #2 (seismic and aircraft crash only)
TA–18–116	Pajarito Site Kiva #3
TA–18–168	Pajarito Site SHEBA Building (seismic and aircraft crash only)
TA–21–155	TSTA
TA–21–209	TSFF
TA–43–1	Health Research Laboratory (HRL) (seismic only)
TA–46–340	Waste Water Treatment Facility (WWTF)
TA–50–1	Radioactive Liquid Waste Treatment Facility (seismic only)
TA–50–37	Radioactive Materials Research, Operations, and Demonstration Facility (RAMROD)
TA–50–69	Waste Characterization, Reduction, and Repackaging (WCRR) Facility
TA–54–G	TWISP (TA–54–229, TA–54–230, TA–54–231, and TA–54–232); Transuranic Waste Storage Domes (TA–54–48, TA–54–153, TA–54–224, TA–54–226, and TA–54–283); Tritium Waste Sheds (TA–54–1027, TA–54–1028, TA–54–1029, and TA–54–1041)
TA–54–38	Radioactive Assay and Nondestructive Test (RANT) Facility
TA–54–39	PCB Waste Storage Facility
TA–54–216	Legacy Toxic Gas Storage Facility
TA–55–4	Plutonium Facility
TA–55–185	Transuranic Waste Drum Staging Building
TA–59–1	Occupational Health Laboratory (worker hazard only)

Facilities that do not perform radiological operations are subdivided into three hazard classes based on the hazard potential of the chemical inventory according to guidance in DOE Order 5481.1B and DOE EM Standard 5502-94 (DOE 1994b). Facilities that do not fall into one of the three hazard classes are considered as nonhazardous facilities (i.e., no hazards identified other than a normal office environment) (LANL 1995a).

The four nonnuclear facility hazard classes are defined as follows (DOE 1994b):

- *High Hazard.* Hazards with a potential for on-site and off-site impacts to large numbers of people or for major impacts to the environment. (Note: There are no facilities at LANL designated by LANL or DOE as High Hazard).
- *Moderate Hazard.* Hazards that present considerable potential on-site impacts to people or the environment but at most only minor off-site impacts.
- *Low Hazard.* Hazards that present minor on-site and negligible off-site impacts to people and the environment.
- *Nonhazardous.* No hazards beyond those routinely encountered in an office environment (electrical equipment, glassware, tools, etc.).

G.3.2.2 *Use of Facility Safety Documentation and Walkdowns*

Based on the results of the accident initiator screening and facility screening, available facility safety documentation was reviewed. All other things being the same, potential accident scenarios with the largest release potential within each frequency row were selected for more detailed review and assessment. Prior to the conduct of facility interviews and walkdowns (in most cases), a preliminary list of accident scenarios was prepared based on facility safety documentation review in order to facilitate the walkdown and discussions with facility operations personnel.

A pre-visit facility walkdown/interview data collection form was prepared for each facility and transmitted to facility representatives (through the LANL SWEIS Project Office). Facility representatives, in coordination with the LANL SWEIS Project Office points-of-contact, then arranged for a facility discussion and walkdown. The walkdown/interview data collection forms were created to facilitate the collection of a consistent set of facility data. In preparing the forms, the previous experience of SWEIS accident analysis team in conducting previous accident evaluations (including safety analyses, probabilistic risk assessments, and process hazard analyses) was considered. In addition, the following specific source documents were considered:

- DOE Handbook 1100-96, *Chemical Process Hazard Analysis*, February 1996 (DOE 1996b).
- DOE EM Standard 5502-94, *Hazard Baseline Documentation*, August 1994 (DOE 1994b).
- DOE Standard 1027-92, *Hazard Categorization and Accident Analysis Techniques for Compliance with DOE Order 5480.23, Nuclear Safety Analysis Reports*, December 1992 (DOE 1992).
- DOE Standard 3009-94, *Preparation Guide for U.S. Department of Energy Nonreactor Nuclear Facility Safety Analysis Reports*, July 1994 (DOE 1994a).

During and subsequent to the walkdowns, revised safety documentation was provided by the facility representatives. This documentation was subsequently reviewed, and a draft data collection document was prepared for each facility. These draft data collection documents were reviewed by the LANL SWEIS Project Office and facility representatives to ensure that the information about the facilities and their operation was correctly noted by the data collection team.

Where a facility had current safety documentation, that documentation was used in the first instance to define accident scenarios. Owing to differences in scope between safety documentation and NEPA accident analyses, some supplementation of the safety documentation was necessary in a few instances in order to provide the required NEPA coverage (this was especially true in the area of seismically initiated sequences). The facility walkdowns were used to further evaluate the accident scenarios identified in the safety documentation, to evaluate whether additional accident scenarios were possible that were not included in the safety documentation, to evaluate whether there were accident frequency or accident consequence mitigation capabilities present that were not credited in the safety documentation, and to assess the impacts of the SWEIS alternatives on the accident scenarios. This latter consideration included the following aspects:

- Evaluation of whether accident frequencies could increase or decrease across the alternatives
- Evaluation of whether the MAR could increase or decrease across the alternatives
- Evaluation of whether accident scenarios identified for the No Action Alternative would be eliminated across the remaining alternatives
- Evaluation of whether any accident scenario not identified for the No Action Alternative would be possible in any of the other alternatives

As a result of the facility walkdowns and interviews and the review of revised safety documentation for many facilities, a large number of credible radiological accident scenarios were identified and grouped by MAR (e.g., weapons grade plutonium, source material plutonium, tritium, highly enriched uranium, depleted uranium, etc.) for further consideration.

G.3.2.3 *Population Distributions*

Population distributions were created (using the SECPOP90 program) based on 1990 Census data for residential population and based on 1996 LANL workforce populations by TA.

LANL workforce populations were included in the analysis by centering the total TA population in the direction from the accident origination facility that represents the largest concentration of TA population for each TA. Although this is an approximation method and results in some double counting because facility workers also may have residences within the 50-mile (80-kilometer) radius of LANL for which consequence calculations were performed, this is believed to be an appropriate means for including LANL workforce consequences.

The aggregation of workforce population data by TA is the only available aggregation for which substantial questions do not exist. Although data are available on a building-by-building basis, those data represent where the LANL employees collect their mail and do not necessarily represent where they spend most of their work day. Neither is the LANL workforce varied across the alternatives for accident analysis purposes, although it is recognized that the LANL workforce varies in size by alternative. There is much greater variation in LANL workforce from shift to shift during any given day than there is across the alternatives. It is not practical nor feasible to refine the population within a TA quite close to a release point because such data are not available and would not be stable. The consequences are given in terms of collective exposure and the exposure at the MEI locations, which are adequate for differentiating among the alternatives for decision making.

In all cases in this accident analysis, the accidents are assumed to take place during the day shift with the maximum workforce population present. (Indeed, the entire workforce is represented in the aggregated workforce population data by TA, not just the daytime workforce.) The assumption of daytime conditions is conservative for those accidents that occur at random and are unrelated to processes in operation at any given time.

G.3.2.4 *Dispersion Parameters Used in Screening and Consequence Calculations*

Daytime populations, which are larger than nighttime populations near the source, were used for screening and calculating the consequences of chemical and radiological accidents. Accordingly, the meteorological conditions used were: (1) wind speed of 9.2 feet per second (2.8 meters per second); (2) Pasquill-Gifford stability Class C; (3) ambient temperature of 48°F (8.9°C); (4) mostly sunny, cloud cover conditions; and (5) 51 percent relative humidity. These are representative of daytime conditions in this area (LANL 1990a). They provide conservative dispersion under daytime conditions and will be referred to as such in this SWEIS. (Class A and B stabilities also occur during the daytime, but their greater vertical air motions will produce lower ground level concentrations. Stable atmospheres, which will produce higher concentrations, can occur but are atypical and therefore not used for screening.)

For the consequence assessment of chemical accidents, both conservative daytime dispersion and adverse dispersion conditions (stable atmosphere) were used. For radiological accidents, all meteorological conditions, in the relative frequency as they occurred in 1995, were used.

G.3.3 Chemical Accident Screening

G.3.3.1 *Summary of Chemical Accident Screening*

Thirty-seven chemicals were identified in the 1992 LANL database that met all of the following criteria:

- Has a time-weighted-average (TWA) less than 2 parts per million
- Is found in readily dispersible form (i.e., a gas or liquid)
- Has a boiling point less than 212°F (100°C) and vapor pressure greater than 0.5 millimeter mercury

These 37 chemicals were modeled for release of their largest 1992 inventory, using adverse dispersion conditions. The ten releases that exceeded the ERPG–3 guideline at 328 feet (100 meters) distance were retained for further analysis. To these were added another eight chemicals of interest.

Releases of the actual inventories of these 18 chemicals at 78 locations were then modeled to see which would exceed the ERPG–3 concentration under conservative daytime dispersion conditions. In this modeling:

- Release was at surface level
- Gases were released over 10 minutes
- Liquids were spilled instantaneously and then evaporated from a puddle 0.4 inch (1 centimeter) deep

The releases that exceeded the ERPG–3 concentration were examined with consideration of:

- Whether there is a large workforce nearby or if there is public exposure
- If a heavy gas, whether the public is protected by intervening canyons

- Whether the consequences are less than a release of the chemical from a different facility
- Whether the consequences are less than those of another chemical released from the same facility

With these considerations, a number of releases were selected and retained for detailed analysis. Formaldehyde also was retained because it represents the largest LANL inventory of a readily dispersible chemical carcinogen. These final selections are shown in Table G.3.3.1–3. The above process is described in detail in the following.

Details of Chemical Screening

There is a wide variety of chemicals in storage and in use at LANL facilities. This analysis assumes that all chemicals that are regulated or have established exposure guidelines are listed in the MULTUS database (Dukes 1995). This commercially available database contains information on over 2,800 controlled chemicals and over 23,000 associated synonyms. Because there are far more TWAs than other guidelines for chemicals, TWAs were chosen to represent toxicity for screening purposes. An upper threshold value of 2 parts per million was selected because it is the TWA for nitric acid. (There is a 6,100-gallon [23,100-liter] nitric acid tank at TA–55 that, because of its volume, was likely to represent the bounding consequence chemical accident.) The MULTUS database was searched for chemicals with TWAs less than 2 parts per million, resulting in a list of 330 chemicals.

The 1992 LANL Automated Chemical Inventory System (ACIS) chemical database (which represented LANL baseline data) was searched for these same 330 chemicals. Only 190 were found. Of these, if the chemical is ordinarily in solid form (nondispersible), it was screened from further analysis. (Although particles smaller than about 10 micrometers diameter are respirable, a liquid or gas is expected to have greater consequences in terms of area of impact and time urgency; thus, the analysis was focused on liquids and gases.) Application of this criterion reduced the list to 74 chemicals.

If the chemical has a boiling point of greater than 212°F (100°C) and has a vapor pressure of less than 0.5 millimeters of mercury under ambient conditions, the material was screened from further analysis. This criterion was developed based on an American Conference of Governmental Industrial Hygienists (ACGIH 1992) hazard index (HI) (which assigns a low vaporization/dispersion hazard to materials with boiling points greater than 212°F [100°C]) and the EPA List of Regulated Substances and Thresholds for Accidental Release Prevention. (The latter establishes a criterion of a vapor pressure of less than 0.02 inch [0.5 millimeter] of mercury under ambient conditions for toxic liquids to capture most substances that have a relatively low volatility but may still pose an airborne hazard in accidental release [40 CFR 68].) Application of this criterion further reduced the list to 37 chemicals.

For each of the 37 chemicals, ALOHA™ dispersion modeling was performed using its largest inventory in the 1992 ACIS database. Adverse dispersion conditions were used to determine whether concentrations as great as ERPG–3 would occur at a distance of 328 feet (100 meters) (the approximate distance to noninvolved workers and general public access). Ten chemicals were found to produce ERPG–3 concentrations at distances beyond 328 feet (100 meters): boron trifluoride, bromine, chlorine, formaldehyde, methyl hydrazine, nitric acid, phosgene, phosphorous oxychloride, selenium hexafluoride, and thionyl chloride.

In addition to the ten chemicals to survive the above screening process, the following seven chemicals were identified in the "significant chemicals in hazard analysis" table of the

LANL hazard assessment document (LANL 1995a), and were included for analysis: diborane, fluorine, hydrogen cyanide, hydrogen fluoride, nickel carbonyl, perfluoroisobutylene, hydrochloric acid, and sulfur dioxide. In addition, a review of the TA–3–170 Compressed Gas Processing Facility inventory resulted in the addition of nitric oxide to the list of chemicals of concern.

An information request was submitted to LANL for storage locations, quantities, physical form, units of measurement, and other associated information for these 18 chemicals. Upon receipt of the information from LANL, the materials were aggregated into storage locations, converted into common units of measurement, and adjusted for concentration. This process resulted in 183 chemical sources at 78 storage locations. The resulting chemical inventories were then modeled to determine which facilities contained total quantities that, if released, would exceed ERPG–3 concentrations at 328 feet (100 meters) under conservative daytime atmospheric dispersion conditions. This modeling identified chemical sources at the storage locations shown in Table G.3.3.1–1.

The initial data source, as indicated above, was the 1992 ACIS baseline data. The following information sources were utilized to find additional storage locations and potential release sites for these chemicals:

- The 1995 ACIS Database, which contains a listing of the chemicals ordered on an annual basis
- TA–54 Area L (hazardous waste management facility) gas cylinder inventory
- STORES Database
- Cheaper Database (recycled chemicals) and Gas Plant Database
- Facility-Specific SARs, Safety Assessments (SAs), and other safety documentation

TABLE G.3.3.1–1.—*Preliminary ALOHA™ Chemical Screening Results*

CHEMICAL	LOCATION
Sulfur Dioxide	TA–54–216
Hydrochloric Acid	TA–55–249
Hydrogen Cyanide	TA–3–66
Nitric Acid	TA–50–1
	TA–50–5
	TA–55–4
	TA–59–1
Selenium Hexafluoride	TA–54–216
Chlorine	TA–00–1109
	TA–00–1110
	TA–00–1113
	TA–00–1114
	TA–3–476
	TA–16–560
	TA–33–200
	TA–46–340
	TA–54–1108
	TA–55–4
	TA–72–3
	TA–73–9
Fluorine	TA–54–216
Hydrogen Fluoride	TA–54–216
	TA–55–4

- LANL Spill Prevention, Control and Countermeasure (SPCC) Plan
- Facility interview and walkdown data collection forms

The results in Table G.3.3.1–1 were examined with a further consideration of population distributions surrounding the release sites and, for heavy gases, consideration of whether the potential atmospheric transport to populated areas would be interrupted by canyons. Based on these considerations, a number of release sites were screened from further consideration. The results of this initial binning effort are shown in Table G.3.3.1–2.

The release sites and chemicals surviving this initial binning effort were then plotted on a map

TABLE G.3.3.1–2.—*Preliminary Binning of Chemical Accident Release Sites*

CHEMICAL	RELEASE SITE	PRELIMINARY BINNING COMMENTS
Chlorine	TA–00–1109	Retained for detailed analysis; located on the edge of a neighborhood
	TA–00–1110	Retained for detailed analysis; located on the edge of a neighborhood
	TA–00–1113	Screened; located in a canyon; any impacts bounded by TA–0–1109/1110
	TA–00–1114	Screened; located in a canyon; any impacts bounded by TA–0–1109/1110
	TA–03–476	Retained for detailed analysis; large LANL workforce nearby; intervening canyon prevents heavy gas transport to Los Alamos townsite
	TA–16–560	Screened; located at a site with no public receptors; impacts bounded by TA–03–476
	TA–33–200	Screened; located at a remote site with no public receptors and a very small LANL workforce population (less than 10); impacts bounded by TA–03–476
	TA–46–340	Screened; no credible accidents; release site is in a canyon; heavy gas plume will dissipate prior to reaching distant public receptors
	TA–54–1008	Screened; located at a remote site with no public receptors; impacts bounded by other chemicals released from TA–54–216 (closer to LANL workforce)
	TA–55–4	Retained for detailed analysis; intervening canyon prevents transport to public receptors; large LANL workforce population (TA–35, TA–48, TA–50, & TA–55)
	TA–72–3	Screened; located at a remote site with no public receptors; canyon prevents transport of a heavy gas to populated areas
	TA–73–9	Screened; located on a hill; heavy gas transport will be predominantly downslope into a canyon, away from public receptors and LANL workforce at TA–00 locations
Fluorine	TA–54–216	Screened; impacts bounded by sulfur dioxide and selenium hexafluoride
Hydrochloric Acid	TA–55–249	Retained for detailed analysis
Hydrogen Cyanide	TA–03–66	Retained for detailed analysis
Hydrogen Fluoride	TA–54–216	Screened; impacts bounded by sulfur dioxide and selenium hexafluoride
	TA–55–4	Screened; bounded by release of chlorine at the same site
Nitric Acid (80%)	TA–50–1	Screened; impacts bounded by chlorine and nitric acid release at TA–55–4
	TA–50–5	Screened; impacts bounded by chlorine and nitric acid release at TA–55–4
	TA–55–4	Retained for detailed analysis (large LANL workforce population at TA–55)
	TA–59–1	Screened; largest container is 2.6 gallons, bounded by much larger potential releases at other facilities
Selenium Hexafluoride	TA–54–216	Retained for detailed analysis
Sulfur Dioxide	TA–54–216	Retained for detailed analysis; other sites screened, bounded by release at TA–59–216

of Los Alamos County and evaluated based on the population grids (on-site and off-site) surrounding the respective chemical storage location. The population distributions for chemical release sites were generated from 1990 Census data and current LANL TA populations as described above. The evaluation considered the probability that the wind would blow in the direction of the population at the time of release.

In addition, the chemical storage locations were separated into the following bins relating to the potential accident scenario: natural phenomena hazards (e.g., seismic events), process hazards, and man-made hazards. This final binning effort is portrayed in Table G.3.3.1–3.

Formaldehyde at TA–43–1, which was originally screened as resulting in concentrations less than ERPG–3 at 328 feet (100 meters) under conservative daytime dispersion conditions, was added back to the list on the basis that it represents the largest LANL inventory of a readily dispersible carcinogen from the 51 confirmed, suspected and animal carcinogens in the site inventory.

G.3.3.2 *Assumptions Inherent in the Screening*

The following assumptions are inherent in the process:

- All hazardous LANL chemicals are in the MULTUS database.
- All hazardous LANL chemicals of significant inventory are in the LANL ACIS database or otherwise captured in the safety documentation and walkdowns.
- There are no readily dispersible particles that pose significant accident release consequence and that are not otherwise captured in the human health analyses and/or in the site-wide and other accident scenarios.

TABLE G.3.3.1–3.—*Final Chemical Accident Binning*

CHEMICAL	RELEASE SITE	PROCESS HAZARD	MAN-MADE HAZARD	NATURAL PHENOMENA HAZARD	CARCINOGEN
Chlorine	TA–00–1109	X		X	
	TA–00–1110	X		X	
	TA–03–476		X		
	TA–55–4	X		X	
Formaldehyde	TA–43–1			X	X
Hydrochloric Acid	TA–55–249			X	
Hydrogen Cyanide	TA–03–66			X	
Nitric Acid	TA–55–4			X	
Selenium Hexafluoride	TA–54–216	X	X		
Sulfur Dioxide	TA–54–216	X	X		

Note: These releases are heavy gas releases except for selenium hexafluoride and hydrogen chloride. Heavy gases in high concentrations would not be capable of crossing canyons from mesa to mesa, but would instead flow down into the canyons and proceed downslope. Such diversion into canyons is not modeled by ALOHA™, which is a flat terrain model. Heavy gas behavior has been taken into account manually in the affected population results shown above. The formaldehyde release from TA–43–1 was screened on chemical consequence results. However, it was retained because it represents the largest inventory of a readily dispersible carcinogenic chemical.

- There are no solid (nondispersible) pyrophoric materials posing a release hazard of significant consequence that were not captured or bounded in one of the accidents considered.
- Gases were modeled as a 10-minute release (rather than an instantaneous release) in accordance with the EPA *Risk Management Plan Off-site Consequence Analysis Guidance* (EPA 1996) and the EPA/FEMA/DOT *Technical Guidance For Hazards Analysis* (EPA 1987). However, instantaneous release may be possible for some gases, producing much higher concentrations (though for a shorter time).
- The terrain around LANL facilities is relatively flat in the first several hundred meters, and when not, this does not dramatically change the concentrations from those produced by ALOHA™.
- The surface around LANL facilities is represented by the surface roughness in the ALOHA™ model, which in turn affects the dispersion rate.
- The averaging time inherent in ALOHA™ does not smooth, to an average less than 2 parts per million, dangerously high momentary concentrations that would exist beyond 328 feet (100 meters).

These assumptions are reasonable for screening because the resultant screening is sufficiently conservative to have a reasonable assurance of capturing all chemicals and chemical locations that pose a risk to the public and workers outside the facility.

G.3.4 Facility Radiological Accident Screening

G.3.4.1 *Methodology for Consequence Screening*

To facilitate radiological facility accident screening, integrated population exposure was established as an evaluation criterion. Consequences were calculated for the release of a unit of material and multiplied by the source term magnitude to obtain approximate consequences for screening. The calculations were performed with the MACCS 2 code (as described in section G.2.4) for both ground level releases and elevated releases (which varied from 18.3 to 100 meters, depending on the facility and the scenario of interest). The following distance intervals were used in each of the 16 compass directions: 0 to 1 kilometer, 1 to 2 kilometers, 2 to 3 kilometers, 3 to 4 kilometers, 4 to 8 kilometers, 8 to 12 kilometers, 12 to 20 kilometers, 20 to 30 kilometers, 30 to 40 kilometers, 40 to 60 kilometers, and 60 to 80 kilometers.

G.3.4.2 *Source Terms*

For radiological accidents, there are two source terms of interest: the initial source term and the suspension source term. The initial source term is the radioactive material driven airborne at the time of the accident. The suspension source term is the radioactive material that becomes airborne subsequent to the accident as a result of evaporation, winds, or other processes. For most DOE nonreactor facilities, the dose from inhalation exposure dominates the overall dose from accidents.

Source terms were estimated based on the accident progression for the scenario being considered. DOE Handbook 3010-94, *Airborne Release Fractions/Rates and Respirable Fractions for Nonreactor Nuclear Facilities* (DOE 1994d), was used as the primary reference for calculation of source terms. DOE Standard 3014-96 (DOE 1996c), which covers aircraft crash accidents, has a separate source term methodology identified in Table II of the standard. Although it is stated to be based on DOE Handbook 3010-94, it is more conservative than the handbook. In order to maintain consistency across the accident analyses, and in accordance with the provision in Section 7.2.5 of the DOE standard, which provides that other methods can be used if justified, the DOE Handbook 3010-94 source term methodology has been applied to the aircraft crash accidents in this SWEIS.

MAR estimates were obtained from safety documentation and verified during the course of facility walkdowns. Two source term equations are used: one for the initial source term and one for the subsequent continuing suspension source term. The initial equation has the following general form:

Initial Source Term = (MAR) x (DR) x (ARF) x (RF) x (LPF)

where:

MAR = Material-at-risk (quantity of material available to be acted on by a given physical stress)

DR = Damage ratio (the fraction of the MAR actually impacted by the accident-generated conditions)

ARF = Airborne release fraction (the fraction of the material suspended in the air as an aerosol and, thus, available for transport due to the physical stresses from a specific accident or due to operation of HVAC systems)

RF = Respirable fraction (the fraction of the aerosols that can be transported through the air and inhaled into the human respiratory system, commonly assumed to include particles of 10 micrometers aerodynamic equivalent diameter or less)

LPF = Leak path factor (the fraction of the respirable aerosols transported through some confinement or filtration mechanism)

The suspension source term equation has the following general form:

Suspension Source Term = (MAR) x (DR) x (ARR/hr) x (24 hrs) x (RF) x (LPF)

where:

MAR = Material-at-risk

DR = Damage ratio

ARR/hr = Airborne release rate per hour

RF = Respirable fraction

24 hrs = Suspension calculational time period

LPF = Leak path factor

Note that the suspension source term includes all processes whereby material continues to become airborne. This includes evaporation of liquids, continuing leaks, and resuspension by air motions of material initially deposited. It is referred to as “suspension” to delineate it from resuspension, a term reserved for resuspension of deposited materials previously airborne.

G.3.4.3 *Identification of Accident Scenarios*

Two primary types of data sources were used for radiological accident analysis: (1) safety documentation, including SAs, hazard analyses (HAs), process hazard analyses (PrHAs), PRAs, and SARs; and (2) facility walkdown/interview data collection forms. Documentation relied upon for the radiological facility accident analysis included the following:

- The draft facility descriptions and hazard classification document for LANL, prepared by the LANL SWEIS Project Office (LANL 1995a)
- Descriptions of alternatives for key facilities prepared by the LANL SWEIS Project Office (LANL 1997c and LANL 1998a)
- The LANL seismic hazard evaluation (Wong et al. 1995)
- The LANL aircraft crash hazard evaluation (LANL 1996c)

- Various LANL memoranda and miscellaneous documentation
- Basis for Interim Operation, Operational Safety Requirements, and Technical Safety Requirements for various LANL facilities
- Environmental Assessments (EAs) and EISs
- Various DOE guidance documents
- DOE orders and standards
- Other nuclear industry data sources (e.g., Swain and Guttmann 1983 and Mahn et al. 1995)

Based on the results of the review of facility safety documentation and the facility walkdown/interview data collection process, a large suite of accident scenarios were identified and their consequences quantified by conservative screening methods. Table G.3.4.3–1 provides a consolidated listing of all of the various scenarios that were subjected to the conservative consequence screening analysis. Only those scenarios that were shown on a conservative screening basis to be potentially risk-dominant were then subjected to a more detailed analysis. (These are listed in Table G.4–1).

G.3.4.4 Addition of Site-Wide Wildfire to Screening Results

In the screening methodology, wildfire was not put into the list of natural phenomena hazards that might initiate accidents. Instead, the DOE initially treated wildfire as a subset of manmade fires (Table G.3.1–1). Manmade fires were considered at individual facilities, but were eliminated as the most frequent accident initiator, or the bounding or representative accident for the facility. Because of this, and because wildfires are not common in facility-specific hazard analysis documents, site-wide wildfires escaped consideration in the Draft SWEIS. At the same time, there was a general recognition of the threat to LANL, as evidenced by the multiple agency cooperation in an ongoing fuel reduction effort. This oversight was brought to the DOE's attention during the public hearings on the Draft SWEIS, and an analysis was immediately begun with input from the Española District of the Santa Fe National Forest, the Bandelier National Monument of the National Park Service, the Los Alamos Fire Department, and LANL departments and personnel. The final analysis appears as SITE–04.

G.3.5 Worker Accident Screening

Analysis of worker accidents was performed to provide estimates of potential health effects from chemical and radiological exposure for involved workers. (For purposes of this SWEIS, workers within the TA where the accident occurs are defined as "involved workers," and other on-site LANL employees are defined as "noninvolved workers.") Because worker health risk from industrial accidents (falls, electrical shock, crushing, etc.) dominates over worker health risk from exposure from radiological and chemical accidents, worker accident analysis is not as extensive or detailed as that for public impacts Also, there are far more low energy events whose impacts are highly dependent upon worker location and the details of the accident.

Worker accidents were reviewed qualitatively in order to arrive at a list of accidents that is representative of the accident potential at LANL under the four alternatives. The process used was similar to the analysis of accidents with public impact. The purpose of the separate worker accident screening was to identify whether there are accident scenarios that could have greater consequence to workers than the worker consequence associated with the public accident scenarios.

Data to support the accident analysis were obtained from a variety of sources, both facility- and site-specific as well as from industrial and

TABLE G.3.4.3–1.—*Consolidated List of Accidents Subjected to Radiological Consequence*

MATERIAL TYPE	HAZARD TYPE (PROCESS, MAN-MADE, NATURAL PHENOMENA)	FACILITY AND SCENARIO DESCRIPTION	ANNUAL FREQUENCY BIN
Highly Enriched Uranium, Depleted Uranium, Plutonium, Tritium, TRU	Natural Phenomena	Multiple facilities, site-wide earthquake resulting in structural damage or collapse	10^{-6} to 10^{-4}
Highly Enriched Uranium	Process	TA–3–29, fire/explosion in ULISSES solvent extraction line or HEU foundry	10^{-4} to 10^{-2}
	Process	TA–3–29, inadvertent criticality event due to multiple procedural violations and/or equipment failures	
	Man-Made	TA–3–29, aircraft crash and fire	10^{-6} to 10^{-4}
	Process	TA–18–116, power excursion leading to fuel melting	10^{-6} to 10^{-4}
	Process	TA–3–66, foundry fire	10^{-4} to 10^{-2}
Plutonium	Man-Made	TA–3–29, natural gas pipeline failure, ingestion of gas into building, explosion and fire	10^{-6} to 10^{-4}
	Process	TA–18–116, reactivity excursion, melting of Pu sample	10^{-6} to 10^{-4}
	Man-Made	TA–50–1, nonprocess-related boiler explosion, damage to clariflocculator	10^{-2} to 10^{-1}
	Process	TA–55–4, inadvertent criticality event due to multiple procedural violations and/or equipment failures	10^{-6} to 10^{-4}
	Process	TA–55–4, ion exchange column exothermic reaction and explosion, failure of HEPA filters	10^{-6} to 10^{-4}
	Process	TA–55–4, explosion and fire in hydride-dehydride glovebox, failure of HEPA filters	10^{-6} to 10^{-4}
	Process	TA–55–4, human error resulting in dropped plutonium oxide powder container, failure of HEPA filters	10^{-4} to 10^{-2}
	Process	TA–55–4, fire in heat source plutonium glovebox, fire suppression inoperable, HEPA filtration ineffective	10^{-6} to 10^{-4}
	Process	DARHT, inadvertent detonation	$< 10^{-6}$
	Process	DARHT, loss of containment	10^{-7} to 10^{-6}

TABLE G.3.4.3–1.—*Consolidated List of Accidents Subjected to Radiological Consequence*-Continued

MATERIAL TYPE	HAZARD TYPE (PROCESS, MAN-MADE, NATURAL PHENOMENA)	FACILITY AND SCENARIO DESCRIPTION	ANNUAL FREQUENCY BIN
Depleted Uranium	Process	TA–3–66, foundry fire	10^{-4} to 10^{-2}
Tritium	Process	TA–16–205, inadvertent opening of LP–50 container	10^{-2} to 10^{-1}
	Process	TA–16–205, high pressure gas handling system failure, ventilation isolation failure	10^{-4} to 10^{-2}
	Process	TA–16–205, tritium waste treatment system failure, ventilation isolation failure	10^{-4} to 10^{-2}
	Process	TA–21–155, release of tritium from nonsecondary contained system during maintenance, or release of tritium from glovebox due to leaking component	10^{-2} to 10^{-1}
	Process	TA–21–155, distillation column failure, vacuum jacket failure, fire	10^{-6} to 10^{-4}
	Process	TA–21–155, tritium leak, tritium waste treatment system failure	10^{-4} to 10^{-2}
	Man-Made	TA–21–155, aircraft crash and fire	10^{-6} to 10^{-4}
	Process	TA–21–209, molecular sieve regeneration error	10^{-4} to 10^{-2}
	Man-Made	TA–21–209, aircraft crash and fire	10^{-4} to 10^{-2}
	Man-Made	TA–54–1027, TA–54–1028, TA–54–1029, and TA–54–1041, unsuppressed wild fire, aircraft crash and fire, or truck fuel system leak and fire at tritium waste storage sheds	10^{-6} to 10^{-4}
	Process	TA–55–4, special recovery line de-inerting and fire	10^{-6} to 10^{-4}
TRU Waste	Man-Made	TA–50–37, aircraft crash and fire	10^{-4} to 10^{-2}
	Process	TA–50–69, TRU waste drum puncture by forklift outdoors	10^{-4} to 10^{-2}
	Man-Made	TA–50–69, truck fuel system leak and fire at outdoor container storage area	10^{-4} to 10^{-2}
	Man-Made	TA–54–38, truck fuel system leak and fire at outdoor container storage area	10^{-4} to 10^{-2}
	Man-Made	TA–54–229, TA–54–230, TA–54–231, and TA–54–232, aircraft crash and fire or unsuppressed wild fire at TWISP storage domes	10^{-6} to 10^{-4}

nuclear generic databases and compilations. Data sources included the following:

- Safety and hazard analysis documentation
- Data forms generated during the facility walkdowns
- LANL SWEIS alternatives documentation: generic data from industry and nuclear facilities including the following:
  - — *Component Failure Rate Data with Potential Applicability to a Nuclear Fuel Plant* (Dexter and Perkins 1982)
  - — *General Component Failure Data Base for Light Water and Liquid Sodium Reactor PRAs* (Eide et al. 1990)
  - — *Handbook of Human Reliability Analysis with Emphasis on Nuclear Power Plant Application* (Swain and Guttman 1983)
  - — *Natural Phenomena Hazards Modeling Project: Seismic Hazard Models for Department of Energy Sites* (Coats and Murray 1984)
  - — Office of Nuclear and Facility Safety, Office of Environment, Safety and Health, U.S. Department of Energy, Washington, DC. Maintains and compiles a series of databases and reports on worker accidents in DOE facilities, including: (1) Occurrence Reporting and Processing System (ORPS) reports for LANL and other DOE facilities; (2) Office of Operating Experience Analysis and Feedback, Safety Notices; and (3) Office of Operating Experience Analysis and Feedback, Operating Experience Weekly Summary
  - — Occupational Safety and Health Administration Form 200 Injury/Illness Reports for LANL and other DOE facilities

The summary listing identified more than 600 potential worker accident scenarios. Potential worker accident scenarios were then sorted by material hazard and initiators and ranked according to relative risk. Risk was qualitatively assigned on the basis of the frequency and consequence ranking matrix for hazard evaluation described in DOE Standard 3009-94 (DOE 1994a) and shown in Figure G.1.1–1. The array of worker accidents was not dissimilar from the array of accidents with public impact, so that the worker accident component of the selected public accidents also provides a representative picture of the worker accident potential.

There are, however, some accidents that pose risk to workers but not to the public. An example is the medical research at TA–43–1, field work on small mammal capture and blood sampling, where the exposures to workers are localized and the exposure to the population from a release would be mitigated by environmental attenuation. Another exception is energetic hazards, where potential hazardous sources do not involve the public. Examples of energetic hazards are:

- High explosives
- Laser
- Pressurized gas
- Radiofrequency
- Liquid nitrogen/cryogen
- Neutron generator
- High pressure
- Hydrogen

Representative energetic hazard accidents include:

- Low pressure steam line failures (TA–16–205)
- Failure of cryogenic systems (TA–3–170, liquid nitrogen and liquid argon; TA–3–1698, liquid nitrogen; TA–16–205, liquid nitrogen; and TA–21–155, liquid nitrogen)
- Rupture of nontoxic gas bottles (TA–15–184, TA–50–1, TA–50–69, TA–54–39, and TA–59–1)

- Failure of noncombustible gas tube trailer (TA–3–29 and TA–50–69)
- Failure of pressurized gas lines (TA–16–205, TA–16–411)
- Electrical shock (all facilities)
- Laser accidents (TA–3–1698)
- Electromagnetic fields (TA–15–312 and TA–53)
- High explosive detonation (TA–15–184, TA–15–312, TA–16–260, TA–16–340, and TA–16–411)

The ranked worker accident scenarios were then compared to the public impact accidents with comparable risk rankings. From the review of the chemical and radiological accidents selected for detailed quantification of public risk, as well as a screen of these accidents against the worker accidents, the following worker accidents were selected for more detailed evaluation:

- Inadvertent high explosives detonation
- Biohazard contamination of a single worker
- Inadvertent criticality event
- Inadvertent exposure to electromagnetic radiation (x-rays, accelerator beam, laser, or RF source)

G.4 EVALUATION OF RISK-DOMINANT ACCIDENTS

The risk-dominant accidents that were selected for detailed evaluation and impact quantification are shown in Table G.4–1. These are five site-wide accidents (earthquakes of varying severity and a wildfire), six chemical accidents, sixteen radiological accidents, and four worker hazard accidents.

G.4.1 Accident Frequency Assessment

This section contains the methodology used to determine the frequency of the different accident scenarios. The resulting frequencies, summarized in Table G.4.1–1, cover a wide frequency range. To place these frequencies in perspective, Table G.1.5–1 (section G.1 of this chapter) gives the probability of some natural phenomena at LANL and the probability of large meteors impacting somewhere in the world.

G.4.1.1 *Earthquake Frequencies*

The frequency of accidents arising from earthquakes is predicated upon a methodology set forth in DOE Standard 1020-94, *Natural Phenomena Hazards Design and Evaluation Criteria for Department of Energy Facilities* (DOE 1994e). Conceptually, the earthquake accident frequency assessment considers two parameters: (1) the frequency per year that earthquakes of different ground acceleration levels occur and (2) the conditional probability of component or structural failure, given those ground accelerations.

In practice, facilities are designed for earthquakes according to their hazard potential. The design for general industry is based on the Uniform Building Code (UBC), which has evolved considerably over the period of time during which currently active facilities at LANL have been constructed (early 1950's through the 1990's). DOE nuclear facilities have design basis earthquake standards (depending upon the hazard potential of the facility) and performance requirements for avoiding hazardous material releases.

The treatment of earthquakes in facility safety documentation varies from the simple (screening earthquakes based on meeting the design basis earthquake guidance) to the bounding (assuming complete structural collapse) to the detailed (seismic margin analysis). In order to try to place the assessment of system and structural response for all LANL facilities on a consistent basis, estimates were made of a parameter known as the high confidence in low probability of failure (HCLPF). This is the ground acceleration level at which the analyst is very confident that the probability of failure is very low. The HCLPF value can be mathematically related to the seismic hazard (annual frequency of ground acceleration) to produce a point estimate of frequency at which system or structural failure will occur.

The seismic hazard at LANL was the subject of a state-of-the-art probabilistic seismic hazard analysis (PSHA) prepared for the laboratory and DOE by Woodward-Clyde Federal Services. The methodology used in the study is similar to (but more advanced in some areas) that approved by the U.S. Nuclear Regulatory Commission (NRC) for commercial nuclear power plant sites located east of the Rocky Mountains. The PSHA produces a variety of results expressing the annual frequency of ground motion at the LANL site. Among the more important results and implications of the LANL PSHA are the following:

- Many important facilities at LANL were designed and constructed in the 1950's through the late 1970's and do not compare favorably with current DOE seismic design requirements.

TABLE G.4–1.—*Risk-Dominant Accidents at LANL*

PROCESS HAZARD ACCIDENTS	
CHEM–01	Single cylinder release of chlorine (150 pounds) from a potable water chlorinator (TA–00–1109, bounding) due to equipment failure or human error during chlorine cylinder replacement or maintenance activities
CHEM–03	Single cylinder release of chlorine (150 pounds) from toxic gas cylinder storage facility (TA–3–476) due to human error during cylinder handling or cylinder deterioration due to unintended long-term exposure to weather
CHEM–06	Chlorine gas release (150 pounds) from a process line at the Plutonium Facility (TA–55–4) due to mechanical damage to a supply manifold
RAD–03	Reactivity excursion accident at Pajarito Site Kiva #3 (TA–18–116) with Godiva-IV outside the kiva, vaporizing part of the highly enriched uranium fuel and melting the remainder
RAD–04	Inadvertent detonation of a plutonium-containing assembly at or near the DARHT Facility firing point, resulting in an elevated, explosive-driven release of plutonium (TA–15)
RAD–09	Transuranic waste drum failure or puncture at TA–54, Area G (bounding)
RAD–10	Plutonium release from a degraded storage container in the Plutonium Facility (TA–55–4) vault during container retrieval (Note: Determined by detailed analysis to be a worker accident only.)
RAD–11	Container breach after detonation of a plutonium-containing assembly at the DARHT firing point (TA–15), resulting in a ground-level release of plutonium
RAD–13	Plutonium melting and release accident at Pajarito Site Kiva #3 (TA–18–116)
RAD–14	Plutonium release from ion exchange column thermal excursion at TA–55–4 (Note: Determined by detailed analysis to be a worker accident only.)
RAD–15	Plutonium release from hydride-dehydride glovebox fire at TA–55–4 (Note: Determined by detailed analysis to be a worker accident only.)
WORK–01	Worker fatality due to inadvertent high explosive detonation
WORK–02	Worker illness or fatality due to inadvertent biohazard contamination
WORK–03	Multiple worker fatality due to inadvertent nuclear criticality event
WORK–04	Worker injury or fatality due to inadvertent electromagnetic radiation exposure (x-ray, accelerator beam, laser, or RF source exposure)
MAN-MADE HAZARD ACCIDENTS	
CHEM–02	Multiple-cylinder chlorine release (1,500 pounds) due to explosion or unsuppressed fire affecting a toxic gas storage facility (TA–3–476)
CHEM–04	Single cylinder release of toxic gas (selenium hexaflouride, historical bounding chemical) from the legacy toxic gas storage facility (TA–54–216) due to random cylinder failure or a forklift accident
CHEM–05	Cylinder release of toxic gas (sulfur dioxide, historical bounding chemical) from the legacy toxic gas storage facility (TA–54–216) due to a fire, a propane tank boiling-liquid expanding vapor explosion (BLEVE), or a propagating random failure
RAD–01	Plutonium release due to container storage area fire involving transuranic waste drums (TA–54–38)
RAD–02	Plutonium release due to natural gas pipeline failure near TA–3–29, with no immediate ignition, ingestion of gas into facility, followed by explosion and fire
RAD–05	Aircraft crash with explosion and/or fire at TA–21 resulting in a tritium oxide release

TABLE G.4–1.—*Risk-Dominant Accidents at LANL*-Continued

RAD–06	Aircraft crash with explosion and/or fire at TA–50–37, resulting in a plutonium release from transuranic waste drums (Note: Retained based on preliminary calculations; final calculations determined that this accident screened on frequency less than 1 x 10^{-7} per year.)
RAD–07	Plutonium release due to container storage area fire involving transuranic waste drums (TA–50–9)
RAD–08	Aircraft crash with explosion and/or fire at the transuranic waste dome area at TA–54 (TA–54–229, TA–54–230, TA–54–231, and TA–54–232)
RAD–16	Aircraft crash with explosion and/or fire at TA–3–29 resulting in a plutonium release
NATURAL PHENOMENA HAZARD ACCIDENTS	
SITE–01	Site-wide earthquake, resulting in damage to low capacity structure or internal components at multiple facilities
SITE–02	Site-wide earthquake, resulting in damage to moderate capacity structures or internal components at multiple facilities
SITE–03	Site-wide earthquake, resulting in structural damage or collapse to all facilities
SITE–03, Surface Rupture	Site-wide earthquake with accompanying surface rupture on subsidiary faults, resulting in structural damage or collapse to all facilities
SITE–04	Site-wide wildfire, consuming combustible structures and vegetation.
RAD–12	Plutonium release from a seismically initiated event

- Earthquakes simultaneously affect all LANL facilities.
- All risk-significant facilities at LANL are located within 3.5 miles (5.6 kilometers) of the Pajarito Fault, which runs parallel to the western boundary of LANL and slopes down-to-the-east under the laboratory. The Pajarito Fault, along with the Embudo Fault (which runs to the north of LANL), is the principal source of large ground motions at LANL.
- The PSHA indicates that, for all eight LANL locations for which detailed calculations were performed, the frequency of a 1.0 g (where "g" is the acceleration due the Earth's gravity) peak horizontal ground acceleration is approximately 1 x 10^{-5} years (about once in one hundred thousand years), which is both well within the bounds of what is considered to be "credible" under NEPA (DOE 1993a) and large enough to heavily damage essentially all LANL facilities.

In order to evaluate earthquake damage to LANL facilities, HCLPF values were estimated based on a variety of sources of information, including detailed seismic margin studies[1] (e.g., TA–3–29 and TA–55–4) and safety documentation. Where no detailed information was available, HCLPF values were based on expert judgment and facility walkdowns. The HCLPF values were mathematically related to the PSHA results such that the HCLPF value is directly related to an annual frequency of occurrence. When this was done, the frequencies of failure of the facilities fell into three groupings for which the frequencies of occurrence differ by only a factor of 3 to 4 within the group. Considering the approximate method used to generate the results, this is considered to represent appropriate groupings for accident analysis purposes. The three earthquake scenarios, and their corresponding frequencies, are as follows:

- SITE–01, HCLPFs ranging from 0.04 g to 0.10 g, with a frequency of 3 x 10^{-3} per year, corresponding to failures of components and structures with relatively low seismic capacities.
- SITE–02, HCLPFs ranging from 0.10 g to 0.25 g, with a frequency of 4 x 10^{-4} per year, corresponding to failures of components and structures with moderate seismic capacities.
- SITE–03, HCLPFs ranging from 0.25 g to 0.44 g, with a frequency of 7 x 10^{-5} per year, corresponding to failure of components and structures with comparatively high seismic capacities.

Seismic studies recently completed and currently in progress have further evaluated the potential for ground faulting. These studies indicate the possibility of such events is low, but credible, at some locations on the LANL site. In addition, the potential of ground faulting at one facility of concern, the CMR Building, will be discussed as a subsection of the SITE–03 event. Section 4.2.2.2 (in volume I, chapter 4) and appendix I discuss further the recently completed studies and their implication for LANL and DOE.

In practice, with significant analytical resources assigned, it would be possible to derive robust HCLPF values and then convolve that information with the seismic hazard curve to identify failure frequencies for all important LANL facilities. However, even were this done, the uncertainties in the results would be substantial due to the uncertainty in the seismic hazard. For example, the range in ground acceleration from the 5^{th} to the 95^{th} percentile, result at a frequency of 1 x 10^{-5} per year, is from 0.55 g to more than 1.0 g. The representation of the earthquake risks by using the three site accidents identified above provides a reasonable level of resolution for the purposes of NEPA accident analysis.

1. A Seismic Margin Study is a study undertaken to quantify the ability of a structure, system, or component to withstand an earthquake greater than it was designed for and still achieve its function.

G.4.1.2 *Fire and Other Accident Frequencies and 1969 Rocky Flats Fire*

Accident frequency assessments were performed for accidents other than those caused by earthquakes and aircraft crash using PRA-based methods and available LANL and industry data sources. The accidents were examined in a step-by-step method that carefully examined the sequential progression of the accidents, beginning with an initiating event and continuing through the chain of equipment failures, human actions, and phenomenological events that constitute the accident scenario. General guidance for such calculations is provided in a Sandia National Laboratories (SNL) publication (Mahn et al. 1995), and this general guidance has been supplemented by numerous LANL-specific and other studies in order to provide a defensible basis for the accident frequency analysis.

It should be recognized that the DOE safety analysis guidance does not require PRA calculations to be performed in order to categorize the likelihood of accident scenarios (DOE 1994a). Rather, coarse binning efforts are undertaken to qualitatively rank the accident scenarios into frequency bins for the purposes of hazards analysis.

Fire other than from earthquake and aircraft crash was postulated to release MAR in several of the analyses (e.g., RAD–01 and RAD–07). A truck fire was considered more likely than other fire initiators (such as wildfire, lightning, and forklift fires) in outdoor areas and was used. However, a leaking fuel system on a truck that goes unnoticed long enough to pool a large amount of fuel, then followed with an ignition capable of igniting the nonvolatile diesel fuel, has a low frequency that is difficult to quantify. The same is true for wildfire in paved areas and for fires initiated by lightning. However, these accidents were retained for analysis because the combined frequency of fires from all causes is thought to pose a credible accident. (The explosive potential of diesel fuel tanks on trucks and other vehicles is very small and was screened out by more likely accident initiators at facilities where trucks might visit.)

In the Final Programmatic Environmental Impact Statement for Stockpile Stewardship and Management (SSM PEIS) (DOE 1996f) the reassignment of pit manufacturing to LANL was analyzed. In the resulting Record of Decision (ROD) (61 CFR 68014), DOE discussed the decision made, that is, to move pit manufacturing to LANL. Historically, pit manufacturing was conducted at the Rocky Flats Plant (now known as the Rocky Flats Environmental Technology Site [RFETS]). At RFETS, a major fire occurred in 1969, and minor fires occurred on other occasions in similar accidents. Plutonium was released in the 1969 fire-related accident.

To provide a better idea of the differences between the operations at Rocky Flats in 1969 and the operations in TA–55 today, a description of the 1969 Rocky Flats fire, as provided by the Atomic Energy Commission (AEC) at the time of the fire, is provided below (AEC 1969). This description includes the findings presented by the AEC. These findings have since been used to improve design characteristics and operating procedures in all DOE nuclear facilities. Thus, a similar sequence of events would not be possible either because of built in barriers that would restrict the initiation of such an event or would prevent the propagation of such a fire.

The LANL Plutonium processing facility, TA–55–4, was designed to correct the deficiencies that led to the 1969 Rocky Flats fire. In the following discussion, the AEC findings are crosswalked to design features and operating procedures that exist in TA–55 today. As demonstrated in this crosswalk, if the preventative measures that exist in TA–55 today were present at Rocky Flats in 1969, the major fire that resulted in release of plutonium would not have happened.

Fire is always a concern when working with any pyrophoric material such as plutonium. However, TA–55 was designed with specific engineering features to prevent fire and is where plutonium has been worked with, handled, and stored for many years. Its past and current research and development missions have been specifically focused on understanding plutonium and its material properties. Introducing pit production at Los Alamos, therefore, does not dramatically increase the potential for fire because TA–55–4 is where plutonium has been stored, handled, and processed since the facility's original inception.

In fact, the fire at Rocky Flats began in a process development area not a production area. The major differences in TA–55–4 that prevent a building-wide fire are specific operating procedures and design features (barriers) that were established based on lessons learned from fires such as that which happened at Rocky Flats. These barriers prevent the fire from starting, as well as prevent its spread should a fire start. As presented in the following discussion, the inference that TA–55–4 will have a building wide fire now that the facility is producing pits is misleading.

Description of the 1969 Fire at the Rocky Flats Plant

The available evidence indicates that the fire originated on the lower shelf of the storage cabinet in Glovebox 134-24 (see Figure G.4.1.2–1) in the North Line. Plutonium briquettes (discs 3 inches [8 centimeters] in diameter and 1 inch [3 centimeters] thick of either pressed scrap metal or lathe turnings) and some loose scrap metal were stored in uncovered cans in the storage cabinet. The exact cause of ignition is unknown; however, plutonium in the form of chips or lathe turnings is pyrophoric and caught fire. The heat from the burning plutonium metal evidently caused the storage cabinet, which was constructed mostly of cellulosic laminate material and plastic, to char and generate flammable gases that may have been ignited by burning plutonium. The heat of the burning gases may have ignited other briquettes and initiated a slow burning of the storage cabinet materials, particularly in the cracks between the joined sections of the cellulosic materials. Regardless of the process, the fire spread to the outer surfaces of the cabinet.

The smoke in the exhaust system of the North Line gradually clogged the filters. The flames on the outer surfaces of the cabinet spread to the combustible gloves and plastic windows on Glovebox 134-24. Up to this time, the fire was still undetected by the few people who were in the building that day because the smoke, flames, and heat were contained within the glovebox system. Because the heat detectors were located outside and under Glovebox 134-24 and were insulated by the floor of the storage cabinet, they were incapable of sensing the fire. (Similar detectors elsewhere in the glovebox system subsequently did function, and the alarm was sounded.)

Once the plastic windows of Glovebox 134-24 were breached, the air rushing in fanned the fire and caused it to spread into the North Conveyor Line and into the gloveboxes east of Glovebox 134-24.

The airflow in the North Conveyor Line normally flowed from east to west. However, because of the clogged filters, the airflow in the line reversed and followed the second ventilation system, which was part of the North-South Line and the Center Line. When the fire reached the North-South Line, it turned south because of two factors: a closed metal door in the North Line and the direction of the airflow. On reaching the Center Line, the fire again went east because of the airflow.

The first indication of a fire was an alarm received in the plant's fire station at 2:27 p.m.

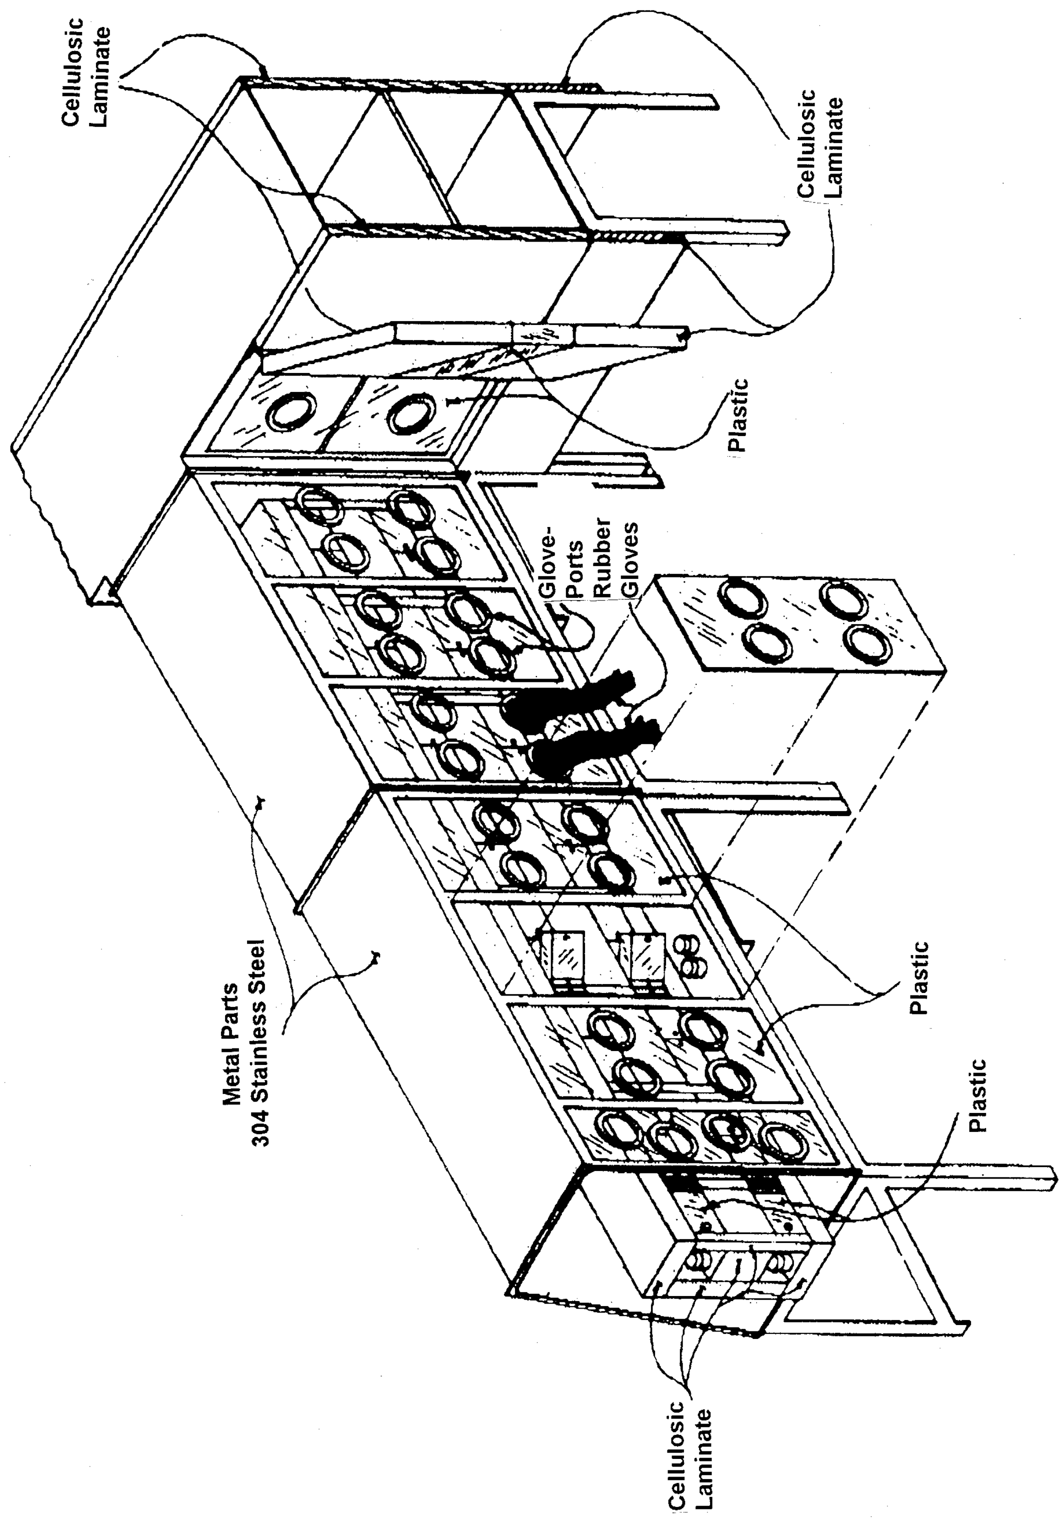

FIGURE G.4.1.2–1.—*Rocky Flats Site, Glovebox 123-24* on May 11, 1969, from the heat-sensing system that monitored temperatures at various locations in the glovebox systems in Building 776-777. Although the fire department responded promptly, the dense smoke, crowded conditions, and presence of large quantities of combustible shielding material made the fire very difficult to fight and extinguish. Because of the concern about the possibility of a nuclear criticality accident (a chain reaction), the standard firefighting procedures then in effect for Building 776-777 did not specify the use of water, except as a last resort. For this reason, there was no automatic sprinkler system in this area of the building. The first attack on the fire was made with carbon dioxide and was ineffective. Less than 10 minutes after the fire alarm was received, the fire captain initiated the use of water. Thereafter, water was used almost exclusively in the firefighting activities. No nuclear criticality occurred. The fire was brought under control about 6:40 p.m., but continued to burn or recur in isolated areas throughout the night.

The damage to Building 776-777 and its equipment was extensive. In addition to the actual fire and smoke damage, the building was heavily contaminated internally with plutonium. Substantial parts of the utility systems within the building were severely damaged. Some of the interconnected buildings sustained minor interior contamination. The fire did not breach the building roof, but slight exterior contamination was measured on the roof of Building 776 and an adjoining building, apparently due to a minor failure of a filter. Instrument readings indicated a level of 0.02 microcuries per 100 square centimeters with a few spots up to 0.2 microcuries per 100 square centimeters. Plutonium also was tracked out of Building 776 by the firefighters and was detectable on the ground around the building. Survey instrument readings in these areas indicated from 0.02 to 0.2 microcuries per 100 square centimeters.

AEC Findings on the May 1969 Rocky Flats Plant Fire

The AEC Report presented the following findings from the May 1969 fire at the Rocky Flats Plant (AEC 1969).

- With the available evidence, the AEC has no basis for concluding that the fire was set intentionally.
- The plastic windows contributed heavily to the spread of the fire and the extent of the loss. These windows, a major structural part of the containment system, provided a fuel surface on the inside of the glovebox-conveyor systems. Continued operation of the glovebox ventilation systems provided a supply of air to support the combustion. Under these conditions, burning of the windows and plutonium would have resulted essentially in the same loss as was experienced even if no other combustible materials had been present.
- Less than 1 percent of the total of almost 600 tons of combustible radiation shielding was consumed in the fire.
- The long interconnected conveyor system without physical barriers provided a path for the fire to spread. The closed metal door in the North Line demonstrated the effectiveness of even a simple firebreak in the line.
- The storage of plutonium briquettes in cans without lids provided potential ignition sources.
- Without the plastic and cellulosic laminate cabinet in Glovebox 134-24, it is unlikely that a plutonium briquette burning in an open metal container would have ignited the plastic windows.
- The addition of the storage cabinet, which nullified the heat-sensing system in Glovebox 134-24, prevented an earlier warning of fire.

Crosswalk of Design Barriers and Operating Procedures Between Rocky Flats in 1969 and TA–55–4 in 1998

The Rocky Flats fire started from the burning of plutonium metal scraps that were stored in metal containers without lids. In TA–55, plutonium is stabilized prior to storage. In this case, storage of scrap material is not permitted in open containers.

The storage containers at Rocky Flats were placed in storage cabinets that were made out of plastic and cellulosic laminate material, providing a fuel source for the burning plutonium. At TA–55, these types of storage cabinets are not used. Studies on combustible loadings are required for all operations that will be conducted within the gloveboxes, and restrictions are placed on the quantities of combustible materials to ensure that fires cannot be sustained and then propagated. Good housekeeping as well as other control measures such as conducting machining operations without oil has lead to a drastic reduction in incipient fires.

Once the fire at Rocky Flats was started, the fire detection systems did not sense the fire because the detectors were located on the outside of the gloveboxes, and the fire in its early stages was confined to the inside of the gloveboxes. Additionally, the glovebox acted to insulate the sensor from the heat of the fire—in effect preventing an early warning. In TA–55–4, the gloveboxes, have sensors both on the inside as well as on the outside of the gloveboxes, and additional sensors exist within the rooms. If the processes within the gloveboxes are modified, it is required to check the sensors to ensure that they have not been blocked.

Once the storage cabinets at Rocky Flats were set on fire, the fire propagated to the plastic gloves and plastic window on the glovebox, burned through, and created a breach in containment. Without the charring of the cabinets and the production of combustible gases, the fire would probably not have spread to the glovebox; however, in this case, the fire was sustained to the point that it could propagate to the glovebox. At TA–55–4 the gloveboxes themselves are required to provide a fire barrier between material in the glovebox and the room itself.

Once the fire at Rocky Flats breached the gloveboxes, there was radiation shielding that surrounded the gloveboxes and the conveyor lines. This material also was combustible, and a small percentage of it burned in the Rocky Flats fire. At TA–55–4 combustible loading within the separate laboratories is kept to a minimum. Also, due to the integration of safety management functions, the solution to one safety concern (such as the use of radiation shielding) is looked at for the potential to cause other safety concerns (such as the propagation of fires). Thus, radiation shielding used at TA–55–4 is not typically flammable.

At Rocky Flats there were no automatic sprinklers in this area of the building due to concerns about a criticality accident. At the time of the fire, the standard firefighting procedure was not to use water, except as a last resort. Within 10 minutes of the fire alarm, the firefighters used water and no criticality occurred. Automatic sprinkler systems are available in TA–55 to stop the spread of fires. In addition, fire water traps, that contain neutron absorbing material, are available to ensure that a criticality event does not occur.

The fire at Rocky Flats propagated east along the conveyor line, turning south following the airflow of the second ventilation system. Continuation of the fire through the North Line conveyor was stopped because of a closed metal door and the prevalent airflow conditions. The glovebox lines in TA–55–4 have automatic dampers that close in the event of a fire. These dampers are at the junction with each trunk line and between rooms. Also, the ventilation system is shutdown in the event of a fire to prevent airflow.

The degree of contamination in the buildings at Rocky Flats was due to regularly spaced plutonium material in the conveyor system and in the gloveboxes. Pit production at TA–55–4 will not come close to the capacity that was required at Rocky Flats. Thus, the amount of plutonium in the gloveboxes will be considerably less than was present at Rocky Flats. The processing lines will be configured in such a manner that a continuous source of exposed plutonium will not be present. Plutonium stored in the gloveboxes also must be in closed containers.

Additionally, Building 776-777 at Rocky Flats did not have an operations center that was staffed 24 hours a day providing full-time monitoring of systems. TA–55–4 has a fully staffed operations center to provide monitoring of systems and alarms on a 24-hours per day basis.

Summary of Differences Between Rocky Flats and TA–55–4

Substantial differences exist between the nuclear facility and operations being conducted in TA–55–4 today and those that were present at Rocky Flats in 1969. The above crosswalk illustrates the barriers that are in place at TA–55–4 that would have prevented the building wide fire at Rocky Flats. TA–55–4 was designed to correct the deficiencies detected in older facilities such as RFETS and is being upgraded to meet the even more stringent requirements of the 1990's, including enhanced seismic resistance and fire containment. Alarms are monitored, and the Operations Center is manned continually at TA–55. The amount of plutonium required for production at LANL is about half that required during RFETS operations. The manufacturing operations are substantively different than those at RFETS, significantly reducing risk. The concern that building wide fires will occur at TA–55–4 due to pit production operations being located at this facility is not plausible considering the controls that exist today.

Consideration of Fires at TA–55–4 in the SWEIS

The SWEIS, however, does consider the potential for fire in TA–55–4. A glovebox fire is analyzed in RAD–14, section G.5.6.14. A glovebox fire is considered credible; but the release of material to the public is not a credible event. A building-wide fire was screened based on the very low probability of propagating a glovebox fire to a laboratory, a laboratory fire to a wing, and a wing fire to the entire building. With the enhancement of pit production, the characterization of accidents at TA–55–4 and, therefore, the risk in operating the site does not change.

G.4.1.3 *Aircraft Crash Frequencies*

This section of the accident appendix presents an analysis of the frequency of an aircraft crash into structures located within the various TAs at LANL. In 1996, LANL issued a study performed by Selvage (LANL 1996c) that used the K. Solomon Model as a basis for aircraft crash frequency assessment. The LANL assessment has been overtaken by subsequent events.

In October 1996, DOE issued a final standard for *Accident Analysis for Aircraft Crash into Hazardous Facilities* that presents a standardized approach (DOE 1996c). The new standard was developed by an inter-agency working group with membership from DOE, the Defense Nuclear Agency, Westinghouse Savannah River Corporation, the Federal Aviation Administration (FAA), the EPA, and the NRC. The working group chairman and an expert panel (with technical experts from private industry, government, and the national laboratories) developed the standard. Technical support teams (data, modeling, structural, and exposure), which also included membership from private industry, government, and the national laboratories, provided technical input and data used in developing the standard. The standard was issued with a number of supporting technical documents for use in safety analysis.

In November 1996, the Final EIS on continued operation of the Pantex Plant and storage of nuclear weapon components was issued by DOE (DOE 1996a). Appendix E of the Pantex EIS included an aircraft crash frequency analysis prepared using the July 1996 draft of DOE Standard 3014. The final version of the DOE aircraft crash standard methodology was applied to LANL facilities to estimate the frequency of an aircraft crash into those facilities (DOE 1996c). Current and projected data describing air traffic are used in the analysis; aircraft traffic rates for Los Alamos Airport traffic reflect projected traffic for the year 2003, which is considered to be a reasonable approximation to the traffic in 2006 (the end of the SWEIS analytical period). The projected air traffic includes air taxi service to Los Alamos Municipal Airport (LAM), although no such service currently exists. This traffic component was retained because air taxi service has existed in the recent past and there is no way of knowing whether it will resume during the SWEIS analytical period extending to 2006.

An estimate of the frequency of an aircraft crash into any of the facilities of interest was generated and is shown in Table G.4.1.3–1. Table G.4.1.3–2 presents the projected number of aircraft operations at LAM.

Site Analysis of Crash Risk

Because there are no alternative sites included in the SWEIS, LANL is the only site that is analyzed with respect to the risk due to aircraft crash. LANL is located within 1 mile (1.6 kilometers) of LAM at its closest point. LAM consists of one runway, which runs from east to west. The primary purpose of LAM is to support the missions of the DOE and LANL (Greiner 1994) Due to local conditions, all takeoffs are to the east, and all landings are to the west. The west end of the runway is only used for runups and taxiing. There is prohibited airspace over LANL (Restricted Airspace R–5101) up to 14,000 feet (4,267 meters). The restricted airspace forces flights taking off from or landing at LAM to follow a path around LANL. During certain inclement weather flight conditions, LANL grants permission to overfly the Live Firing Range (TA–72). To perform this overflight, pilots must receive prior permission, and the firing range ceases operations during the overflight (LANL 1996c).

Note that the DOE standard (DOE 1996c) does not provide for a reduction in crash frequency to account for restricted airspace. Restricted airspace is an administrative control; no physical barriers exist. In the event of an aircraft accident, loss of control is presumed. Thus, the aircraft could, in principle, crash anywhere, including within a restricted airspace. Moreover, flights above 14,000 feet (4,267 meters) can overfly LANL in any event. Thus, while giving no credit to the restricted airspace in terms of reducing crash frequencies may be conservative, the degree of conservatism is not believed to be large enough to warrant a departure from the DOE Standard.

In addition to LAM, there are two airports in the vicinity of LANL. Santa Fe Municipal Airport is located approximately 18 miles (29 kilometers) southeast of LANL. Albuquerque International Airport is located approximately 56 miles (90 kilometers) southwest of LANL. These two airports are outside of the probability density function boundary for all categories of aircraft. Thus, only LAM airport activity and nonairport (in-flight) aircraft were included in the analysis as described in the DOE standard (DOE 1996c).

In this analysis, 1993 data obtained from the *Los Alamos Airport Master Plan* (Greiner 1994) indicate that there are approximately 12,431 operations per year at LAM. This number is split between Ross Aviation operations, permit

TABLE G.4.1.3–1.—*Aircraft Crash Rates*

AIRCRAFT CATEGORY	CRASH RATE	
	TAKEOFF (PER TAKEOFF)	LANDING (PER LANDING)
COMMERCIAL		
Air Carrier	1.9×10^{-7}	2.8×10^{-7}
Air Taxi	1.0×10^{-6}	2.3×10^{-6}

Single-Engine Piston	11,781	5,891	5,891
Multiple-Engine Piston	794	397	397
Turboprop	13	6	6
Turbojet	13	6	6
Total	18,000	9,000	9,000

Source: Greiner 1994

(based) aircraft operations, and transient aircraft operations.

The LAM Master Plan study forecasted future annual aircraft operations of 18,000 for the year 2003. This total includes 5,400 air taxi operations, 10,600 permit aircraft operations, and 2,000 transient aircraft operations. These projected numbers are used in the analysis, assuming half are takeoffs and half are landings.

According to the LAM Master Plan study, more than 99.9 percent of the aircraft forecasted to use LAM are Class A (12,500 pounds or less, single-engine) and B (12,500 pounds or less, multiple-engine) small aircraft. Less than 0.1 percent are Class C (12,500 to 300,000 pounds, multiple-engine), and no Class D (over 300,000 pounds, multiple-engine) aircraft can operate at LAM (Greiner 1994).

Based on the above percentages, the 13,800 general aviation operations were split between the four DOE standard (DOE 1996c) general aviation categories. The LAM Master Plan study indicates that the number of general aviation operations is dominated by "based" aircraft. Because based aircraft are predominately single-engine piston aircraft, the split between single-engine and multiple-engine aircraft was based on the percentage of based aircraft from these classes. Thus, 93.5 percent of the operations were assigned to single-engine aircraft, 6.3 percent to multiple-engine aircraft, and 0.1 percent each to turboprops and turbojets. One hundred percent of the air taxi operations were assumed to be accomplished using DHC–6 Twin Otter aircraft (Greiner 1994). This aircraft is considered an air taxi by the DOE standard technical support material (LLNL 1996). The actual wingspan of this aircraft is 65 feet (20 meters) (Jane's 1995). This wingspan was used in the calculation.

Because LANL TAs are within the aircraft category dependent exclusion distance from LAM, the aircraft operations of interest for this analysis are takeoff, landing, and in-flight modes. The length of the east-west runway at LAM is approximately 1.0 mile (1.61 kilometers). Due to the aircraft category dependent exclusion distance, all aircraft considered as in airport operation on the east-west runway were either in the takeoff or landing mode. For this runway, 50 percent of operations are takeoffs and 50 percent are landings. LANL resides within the aircraft category dependent exclusion distances, so a near-airport analysis was required, and probability density function values were used in this analysis.

The NPf (x,y) values provided in DOE Standard 3014-96 (DOE 1996c) for the various aircraft categories reflect the crashes per square mile, per year, centered at a given site for nonairport operations. In this analysis, the following NPf (x,y) values (in crashes per square mile per year, centered at the site) for LANL were used (DOE 1996c):

NPf (x,y) General Aviation = 2×10^{-4}

NPf (x,y) Air Carrier = 2×10^{-7}

NPf (x,y) Air Taxi = 3×10^{-6}

NPf (x,y) Large Military = 1×10^{-7}

NPf (x,y) Small Military = 5×10^{-6}

These values are specific to the LANL site, and are based on an analysis of the locations of past aircraft crashes within the continental U.S. The data are substantial for general aviation aircraft (over 1,000 crashes), while the available data for other aircraft categories (air carrier, large military, etc.) are very limited. Crash location frequencies for general aviation aircraft were based on the assumption that future levels of activity and flight patterns will be similar to the historical record.

Nonairport commercial and military crash frequencies are based on the assumption that the aircraft will fly point-to-point under the new

FAA regulations, rather than in specific airways. The model for these aircraft assumes that the traffic density within an Air Route Traffic Control Center (ARTCC) is uniform, and that given a crash within the ARTCC, the location of the crash is random. The crash rate is assumed to be uniform for the continental U.S. and proportional to the aircraft traffic volume handled at each ARTCC.

For small military aircraft, however, the number of crashes per year is estimated for each ARTCC based on the distribution of crash locations in the historical record. It is important to recognize that the in-flight analysis for military aviation applies only to normal in-flight operations outside military operations areas and low-level flight ranges.

Frequency of Releases as a Result of Aircraft Crash

It was recognized early in this SWEIS analysis that seismic events can cause simultaneous releases of hazardous materials from multiple facilities at frequencies in the range of 1 x 10^{-5} per year and higher. Accordingly, detailed aircraft crash consequence calculations were only performed if it appeared that the frequency and source term of the aircraft crash accident were risk-significant compared with the seismic event; that is, the products of the consequence and frequency were comparable. In this analysis, facilities that contain plutonium, tritium, and hazardous chemicals were considered.

The DOE Standard 3014-96 (DOE 1996c) provides methodologies for: (1) estimating the frequency of aircraft impact into a facility, based on a conservative, simplified equation; (2) determining the effect of the impact on the facility through structural response analysis; (3) determining the frequency of a release of hazardous materials from the facility, given an aircraft impact; and (4) evaluating the exposure resulting from such a release.

The DOE Standard 3014-96 approach to aircraft crash analysis is intended for use in safety analysis. The methodology provides an approximate level of risk, rather than a detailed risk assessment. As a result, the methodology adopts typical accident analysis practice by addressing uncertainty through the use of analytical margin instead of a formal uncertainty analysis. The focus is on analyzing the risk posed to the health and safety of the public and on-site workers. The standard does not consider the risk to the occupants of the aircraft, the risk to individuals inside a building affected by a crash, nor the risk to other individuals on the ground (either inside or outside a facility boundary) who might be directly impacted by the crash (DOE 1996c). The methodology also does not consider malicious acts (e.g., sabotage, terrorism, and war) (DOE 1996c).

Estimating the frequency of hazardous material releases as a result of aircraft involves a series of calculations of increasing analytical sophistication, to the level required to demonstrate that aircraft crash either does or does not cause a level of risk equivalent to that from other risk sources. The analysis considers the structural properties of the affected facility as well as its inventory of hazardous materials.

Local impacts to facilities include penetration, perforation, and scabbing. Penetration occurs when the missile (flying debris) striking a facility intrudes into the outer surface of the structure. Perforation occurs when the missile punctures a hole all the way through the concrete or steel surface. Scabbing occurs when the missile does not perforate, but does cause concrete to be ejected from inside face of the target into the facility.

Because heavy, high-speed aircraft have much greater potential to damage than do slow, light aircraft, the method requires that the population of aircraft in the skies around the site be resolved into subpopulations by weight and speed. A structural calculation is performed to determine if an aircraft that hits a facility will cause sufficient damage to warrant further analysis. Aircraft missiles (i.e., flying objects from the crash) for the structural calculations are selected by using representative engine weights and diameters. The structural analysis is performed by calculating the scabbing and perforation thickness for each aircraft category into the facility using an empirical model.

The first step in the process is to determine the representative type of aircraft for each category. Next, the effective area of a facility is determined based upon the length, width, and height of the facility and the aircraft's wingspan, flight path angle, heading relative to the heading of the facility, and the length of its skid. Using the calculated area of a facility, the number of operations near a facility, and crash rate density function, the frequency of hitting the facility for each aircraft category is calculated. The total frequency is the sum of all the aircraft category frequencies. If the total frequency of hitting a facility is greater than 1 x 10^{-6}, further analysis is conducted.

The calculations are refined to eliminate aircraft categories that cannot cause a release of hazardous materials, leaving only those that could, through impact and/or fire, release radionuclides or toxic chemicals. If the frequency of hitting a facility and causing either scabbing or perforation is greater than 1 x 10^{-6}, the DOE standard requires that a consequence analysis be performed (DOE 1996c).

Calculation of Facility Effective Area. The total effective area of a facility is the sum of the true area (the facility base area adjusted for aircraft dimension), the shadow area (defined by the facility height and the angle of postulated impact), and the skid area (the area covered by a skidding aircraft after impact with the ground).

The analysis was done on a building-by-building basis, treating each facility individually. The topographic features of the LANL site are such that the actual skid distances can be less than the skid distances given in the DOE standard. Subsequently, the skid distances were reduced based on actual site conditions. The majority of reduced skid distances affect only commercial and military aircraft. The angle of impact chosen was based on the values presented in the DOE standard (DOE 1996c). A total effective area for each facility was calculated using the reduced skid distance.

Table G.4.1.3–3 presents the various building dimensions. Table G.4.1.3–4 presents the aircraft operational data used, including the skid distances. Both the DOE standard and maximum wingspans for aircraft in the vicinity of LAM are given. Maximum wingspans were determined by selecting representative aircraft from *Jane's All the World's Aircraft* (Jane's 1995). The skid distances in the table correspond to the skid distances presented in DOE Standard 3014-96 (DOE 1996c).

Hit Frequency Calculation. Based on the center-line and perpendicular distances to the TA facilities of interest, all aircraft using LAM were analyzed using the near-airport model. The impact frequency was obtained for each facility by multiplying the number of flights, the impact area, the crash rate, and the crash density function for each category. Table G.4.1.3–5 contains the crash frequencies for landings, takeoffs, and the nonairport aircraft for each facility.

Structural Calculation. For this analysis, 70^{th} percentile velocities of aircraft were used (LLNL 1996). The velocities chosen were in either takeoff or landing operations, whichever was the largest. For facilities with overburden, these velocities were reduced according to the earth overburden velocity reduction equation.

The local response equations for rigid missiles impacting reinforced concrete structures were applied to applicable facilities, and the local response steel equations for rigid missiles were applied to applicable facilities. A reduction in penetration depth was taken because the

[a] Note: This is the raw crash frequency for this facility. There is a conditional probability of MAR being present that must be multiplied times the crash frequency to obtain the frequency of a crash with MAR present. The conditional probability is classified for this facility.

[b] Note: This is the raw crash frequency for this facility. There is a conditional probability of MAR being present that must be multiplied times the crash frequency to obtain the frequency of a crash with MAR present. The conditional probability is less than 5 percent.

missiles were nonrigid. In cases where the structural equations presented in the DOE standard do not apply (e.g., due to the facility construction), it was assumed that significant building damage to these facilities was a certainty (i.e., probability of 1, given impact). In this analysis, the aircraft engine was investigated as the missile of concern. These engines were treated in the equations as nonrigid missiles. Table G.4.1.3–6 presents maximum engine weights and diameters for aircraft landing and taking off at LAM. Maximum engine weights and diameters were determined by selecting representative aircraft from *Jane's All the World's Aircraft* (Jane's 1995). Maximum engine weights and diameters were then used in the structural calculations.

Local response structural calculations were performed for the various overburden and building thicknesses. Table G.4.1.3–7 presents the results for perforation.

Perforation and Scabbing Frequency Calculation. For this analysis, it was assumed that for facilities such as the TRU waste domes in TA–54, which are constructed of a rigid arch frame covered by a tensioned membrane, the release frequency due to aircraft crash is the same as the hit frequency. For facilities with high explosives, the bounding accident is a perforation or scab leading to an explosion. For facilities without high explosives, the bounding accident is a perforation leading to a fire. Scabbing leading to an explosion in steel facilities is not possible because steel does not scab. The areas for the facilities were reduced using the structural analysis results. The reduced areas were then used to recalculate perforation and scabbing frequencies. Table G.4.1.3–8 presents the frequencies of perforation leading to an explosion, and Table G.4.1.3–9 presents the frequencies of perforation leading to a fire for landings, takeoffs, and the nonairport aircraft for each facility.

The true, shadow, and skid areas for the various facilities were reduced for perforation and scabbing (Table G.4.1.3–7). If the facility roof does not sustain damage, then the true area is reduced to zero. If the facility walls do not sustain damage, then the shadow and skid areas are reduced to the width of the building times the skid distance.

Note: In the cases of TA–8–22, TA–8–23, TA–15 DARHT, and TA–16–411, there is a conditional probability significantly less than one of MAR actually being present.

Discussion of Aircraft Crash and Release Frequencies

The aircraft crash frequencies in Table G.4.1.3–5 provide an indication of the frequency with which personnel injuries or fatalities could occur as a result of an aircraft crash at the facilities listed in the table. Note that a crash is not necessarily equivalent to a release of hazardous material; however, the conditional probability of a release given a crash is dependent on the design and construction of the facility and the nature of the aircraft impacting the facility.

Two types of release scenarios were considered: perforation leading to an explosion and perforation leading to a fire. The perforation-induced explosion results are presented in Table G.4.1.3–8. The results, particularly when the conditional probability of explosives being present is taken into account, indicate that perforation-induced explosion is a very minor contributor to risk. With the exception of the TA–3–476 facility, the other facilities potentially affected have perforation-induced explosion frequencies of less than 1 x 10^{-8} per year. This frequency is so low compared with the seismic structural damage/collapse scenarios (which can result in a large source term) that perforation-induced explosion is not considered further.

The perforation-induced fire results indicate that four facilities with hazardous materials have perforation-induced fire frequencies above 1 x 10^{-6} per year. The frequency of perforation-induced fire aircraft crash events at these facilities was examined in comparison with the seismic structural damage/collapse scenarios in order to evaluate whether aircraft crash accidents needed to be evaluated in detail.

It is important to recognize that the DOE aircraft crash standard (DOE 1996c) was intended for use as a safety analysis screening tool. For facilities that, after full analysis in accordance with the standard, still have aircraft crash frequencies in excess of the evaluation guidelines in the standard (crash frequency of greater than 1 x 10^{-6} per year), it was intended that a more detailed analysis be performed in order to determine whether aircraft crash should be considered to be an evaluation basis accident for safety analysis purposes. For NEPA purposes, the results indicate that the TA–3–29 (CMR), TA–21–155 (TSTA), TA–21–209 (TSFF), and TA–54 TWISP facilities dominate the aircraft crash-induced release frequency. The releases from TSTA and TSFF due to aircraft crash represent bounding tritium release scenarios for LANL because they occur at a relatively high frequency (compared with other large tritium release accidents) and, because of the accompanying fire, the tritium released would be in oxide form (which is more radiologically hazardous than elemental tritium gas).

Plutonium release from the CMR Building (RAD–16), plutonium release (from TRU waste) at TA–54 TWISP (RAD–08), and tritium oxide release from TSTA/TSFF (RAD–05) due to aircraft crash and fire were retained as risk-dominant accidents.

Having the crash frequency estimates, a consequence analysis was performed for each accident. (An analysis also was conducted for an "incredible" aircraft crash at RAMROD (RAD–06). The consequence analyses are similar to the consequence analyses for other accident scenarios, except that release fractions specified in the DOE aircraft crash standard (DOE 1996c) are used, rather than release fractions from DOE Standard 3010-94 (DOE 1994d).

The remaining perforation-induced fire scenarios identified in Table G.4.1.3–9 are considered to be bounded in risk by seismic release scenarios that occur at a much higher frequency. (Seismic releases occur in the frequency range of to 7.1 x 10^{-5} to 2.9 x 10^{-3} per year; whereas, the remaining aircraft crash with perforation-induced fire releases occur in the frequency range from to 1.3×10^{-10} to 8.9×10^{-7} per year.) For an aircraft crash accident to dominate over a seismic release for the remaining facilities, the source term for the aircraft crash accident would have to be orders of magnitude greater than for the seismic structural damage/collapse. No such release potential was identified.

G.4.2 Accident Source Term Assessment

The "source term" is a description of the physical and chemical characteristics of the materials released inside the facility or to the environment. The source term parameters include not only the MAR and the amount and rate of release, but also parameters that determine the subsequent transport, dispersion, and effects. These include whether the material is gas or particulate, in elemental or oxide form (e.g., for tritium and plutonium), and whether the release occurs at ground level or at some elevation above the ground. The plume source height is determined by the intensity of the fire or explosion, or, if the release is from a stack, the stack parameters (e.g., stack height diameter and velocity, heat content, etc.).

G.4.2.1 *Chemical Accident Source Terms*

Chemical accident source terms are estimated in a straightforward manner for the SWEIS. The screening analysis identified toxic gases and liquids that could easily disperse in the event of an accident. The source terms are based on the MAR quantities appropriate to the accident initiator. For example, in the case of a building structural collapse due to an earthquake, the entire gaseous/liquid chemical contents of the building are assumed to be released. For a process-related accident, such as the failure of a valve on a 150-pound capacity cylinder of chlorine, the source term is the maximum contents of the cylinder (even though it is recognized that the container may not be full when the valve failure occurs).

Where there are physical constraints on the release, these are recognized in the modeling. The 150-pound chlorine cylinder release is a good illustration of this sort of constraint. The chlorine inventory in the cylinder is partially gaseous and partially liquid. When the valve fails, the gaseous chlorine depressurizes very quickly, releasing a jet of liquid. However, this act results in a cooling of the cylinder below the boiling temperature of the liquid chlorine, halting the large release. As a result, not all 150 pounds of chlorine are released quickly. Simulation predicts the release of 68 pounds in the first 45 seconds at a flow rate of 91.5 pounds per minute. The flow rate then decreases sharply (Gephart and Moses 1989). The remaining chlorine would be released slowly as the container heats up to ambient temperature. Such a slow release rate would not pose significant hazards downwind of the release point. This type of release can be modeled with ALOHA™.

In some cases, conservative assumptions must be made in order to model the accident. A good example of this is the fire at TA–3–476, which results in chlorine release by melting fusible plugs in the chlorine cylinders (which melt at 165°F [74°C] and release the chlorine at a pre-defined rate in order to prevent sudden rupture of the cylinder). There are potentially ten affected cylinders in this accident. In reality, not all ten would release at exactly the same time. Due to modeling limitations, however, it was necessary to assume a simultaneous release. This is a conservative and bounding representation of the accident, but is not necessarily the most realistic portrayal of the accident. Table G.4.2.1–1 provides a summary of source terms for the chemical accidents.

TABLE G.4.2.1–1.—*Summary of Chemical Accident Source Term Calculations*

ACCIDENT SCENARIO DESIGNATOR	AFFECTED FACILITY	CHEMICAL RELEASED	SOURCE TERM INFORMATION
CHEM–01	TA–00–1109	chlorine	150 pounds

G.4.2.2 *Radiological Accident Source Terms*

DOE has issued standard guidance on estimating source terms for nonreactor nuclear facility accidents as DOE Handbook 3010-94 (DOE 1994d). (Note: aircraft crash source terms were not calculated using DOE Handbook 3010-94. Rather, DOE Standard 3014-96 specifies the source term methodology for aircraft crash accidents. Although DOE Standard 3014-96 cites DOE Handbook 3010-94 as a basis for its values, there are differences, and DOE Standard 3014-96 was used for aircraft crash accidents.)

DOE Handbook 3010-94 received extensive peer review within the DOE technical community and is the best available current information on the subject. Although the handbook presents both median and bounding values in many cases, this accident analysis employs the bounding values. (Accordingly, where SARs have used more realistic, less conservative source terms, the SARs have projected lesser consequences.) Although the availability of a median and bounding estimate might result in a temptation to generate a statistical distribution of values, the handbook specifically cautions against such an approach (DOE 1994d):

"The generation and suspension of particles is the result of the interaction of multiple physiochemical variables that have not been completely characterized as the majority of the experiments performed were designed in an attempt to reflect reasonably bounding conditions for specific industrial situations of concern. Accordingly, the data obtained are more accurately characterized as selected points from multiple distributions against multiple parameters than as different values from a common distribution. Even if this point is neglected, there are still practically intractable problems in attempting to generate statistical distributions. While the data are presumed to be bounding for the purpose intended, it is largely unknown whether the data values are truly 90^{th} percentile, 99^{th} percentile, 99.9^{th} percentile, etc. Further, in many cases it is considered likely that accident specific ARFs are actually distributed in a highly irregular manner (i.e., multi-modal or truncated distributions). Assuming a typical distribution (i.e., log-normal, Poisson) using standard deviations will produce seriously distorted values that may have little or nothing to do with reality."

The handbook also cautions against over reliance on the values contained therein (DOE 1994d). Table G.4.2.2–1 provides the details of source terms for radiological accidents.

TABLE G.4.2.2–1.—*Source Terms of Radiological Accidents at LANL*

ACCIDENT SCENARIO DESIGNATOR	AFFECTED FACILITY	MATERIAL RELEASED	SOURCE TERM INFORMATION
SITE–01	TA–3–29	Pu-239	96.9 g of Pu-239 initial; 9.4 g suspension

RAD–01	TA–54–38	Pu-239	0.13 Pu-239 PE-Ci initial release (elevated); 0.60 Pu-239 PE-Ci suspension release (ground level)
RAD–02	TA–3–29	Pu-239	504 g Pu-239 released in 60 seconds (explosion), 6 g Pu-239 released in 2 hours (fire), 0.48 g Pu-239 suspension release (ground level)

TABLE G.4.2.2–1.—*Source Terms of Radiological Accidents at LANL*-Continued

ACCIDENT SCENARIO DESIGNATOR	AFFECTED FACILITY	MATERIAL RELEASED	SOURCE TERM INFORMATION
RAD–03	TA–18–116	HEU, Fission Products	7,194 g HEU and fission products initial release (ground level); 56.1 g HEU suspension release (ground level)
RAD–04	DARHT	Pu	Elevated release of Pu
RAD–05	TA–21–155 and/ or TA–21–209	tritium oxide	200 g tritium oxide, elevated release (fire), no suspension release
RAD–06	TA–50–37	Pu-239	0.63 Pu-29 PE-Ci released in 30 minutes (elevated release); 2.8 Pu-239 PE-Ci suspension release (ground level)
RAD–07	TA–50–69 Container Storage Area	Pu-239	0.28 Pu-239 PE-Ci released in 2.4 minutes (elevated); 0.52 Pu-239 PE-Ci suspension release (ground level)
RAD–08	TWISP	Pu-239	0.16 Pu-239 PE-Ci initial release (elevated); 0.74 Pu-239 PE-Ci suspension release (ground level)
RAD–09	TWISP	Pu-239	High activity container, 0.066 Pu-239 PE-Ci initial release (ground level; 0.63 Pu-239 PE-Ci suspension release (ground level); Average activity container, 0.0012 Pu-239 PE-Ci initial release, 0.012 Pu-239 PE-Ci suspension release
RAD–10	TA–55–4	Weapons-Grade Pu	2.7 g weapons-grade Pu initial release (stack); 4.3 g weapons-grade Pu suspension release (ground level)
RAD–11	DARHT	Pu	Ground-level release of Pu
RAD–12	TA–16–411	Pu	Elevated release of plutonium
RAD–13	TA–18–116	Weapons-Grade Pu, Fission Products	6 g weapons-grade Pu initial release, plus fission products (ground level); 0.6 g weapons-grade Pu suspension release (ground level)
RAD–14	TA–55–4	Weapons-Grade Pu	2.5 g weapons-grade Pu initial release (stack); 0.0983 g weapons-grade Pu suspension release (ground level)
RAD–15	TA–3–29	Weapons-Grade Pu	6.6 g weapons-grade Pu initial release; 4.34 g weapons-grade Pu suspension release (Expanded Operations Alternative only)
RAD–16	TA–3–29	Pu-239	0.69 g Pu-239 initial release (elevated); 0.21 g Pu-239 suspension release (ground level)

Note: As plutonium-239 (Pu-239) ages, there is an ingrowth of the daughter americium-241 (Am-241) that affects the gamma radiation levels. However, an analysis shows that health effects from the combined uptake are quite independent of the aging. Therefore, the MAR does not distinguish as to age of the material released.

G.5 ACCIDENT CONSEQUENCE ASSESSMENT

This section provides the detailed description and analysis results for each of the accident scenarios for which impact quantification is performed. Table G.5–1 provides a summary of the consequences to the public from risk-significant accidents at LANL. The annual frequency at which these consequences occur (that is, their probability of occurrence in any year), can be put into a common perspective by reference to Table G.1–2. When the term "societal risk" is encountered, recall that the product of consequence and probability is called societal risk in the SWEIS. It permits the ready comparison of accidents and alternatives without the burden of the details found in this section.

G.5.1 Note on Worker Consequences

Table G.5.1–1 provides a similar summary for consequences to workers in the facilities at which the accidents originate. The consequences are characterized rather than quantified. In most cases, it is possible to estimate the number or range in number of people that may be present as determined from experience, the size of the task, or administrative limits. However, it is not generally possible to quantify the number of injuries and fatalities this close to the source because: (1) the details of the contaminant distribution, fires, projectiles, and explosive forces close to the accident point are not known and are not predictable; (2) the numbers and locations of workers change frequently; and (3) worker response, which has a large effect in increasing or decreasing consequences, is not predictable.

G.5.2 Note on Soil Contamination

There is also soil contamination that results from deposition of plumes from radiological releases. When provided by the model, the predicted mean soil contamination levels are given in tables at the end of the descriptions of those radiological accidents that release more than a small amount of uranium or plutonium. (There is negligible deposition of tritium on soil.) The deposited material may subsequently become airborne by wind or other disturbances. The resulting potential for exposures through inhalation is small compared to the initial plume; nevertheless, the dose from such is calculated in the modeling and is included in the exposures in Table G.5–1.

Over the long term, the soil contamination has potential for further exposure through inhalation of air and ingestion of food products. The federal government, under the Federal Radiological Emergency Response Plan (61 Federal Register [FR] 20944), responds to a radiological emergency and provides resources to assist in the evaluation and mitigation of potential long-term exposure pathways to humans. Specifically, EPA will assume responsibility from DOE for long-term monitoring and remediation, assist in the preparation of area restoration plans, and recommend cleanup criteria. The U.S. Department of Agriculture (USDA) will inspect meat and meat products, poultry and poultry products, and egg products to ensure they are safe for human consumption. In addition, the USDA in conjunction with the U.S. Department of Health and Human Services (HHS) will assist in monitoring the production, processing, storage, and distribution of food through the wholesale level to eliminate or reduce contamination to a safe level. HHS will assist with the assessment, preservation, and protection of human health, and will assist state and local governments in making evacuation and relocation decisions.

TABLE G.5–1.—*Summary of Consequences from Risk-Significant Accidents at LANL*[a]

SCENARIO	DESCRIPTION	BASELINE LIKELIHOOD[b]	BASELINE CONSEQUENCE MEASURES[c]	EFFECT OF ALTERNATIVES[d]
SITE–01	Moderate earthquake. on the Pajarito Fault or a large earthquake in the Rio Grande Rift zone, resulting in structural damage and/or severe internal damage to comparatively low-capacity facilities.	Approximately 2.9 x 10^{-3} per year (i.e., one such event in approximately 350 years).	Mean population dose approximately 27,726 person-rem, resulting in approximately 16 excess LCFs; MEI dose 20 rem; several tens of people exposed at or above ERPG–2 or ERPG–3 levels at distances to a substantial fraction of 1 mile from multiple sources.	NOA—baseline. No difference among alternatives; the MAR and accident conditions are unaffected by the alternatives.
SITE–02	Large earthquake on the Pajarito Fault, resulting in structural damage and/or severe internal damage to low- and moderate-capacity facilities.	Approximately 4.4 x 10^{-4} per year (i.e., one such event in approximately 2,300 years).	Mean population dose approximately 41,340 person-rem, resulting in approximately 24 excess LCFs; MEI dose 34 rem; approximately 100 people exposed above ERPG–2 or ERPG–3 levels to a distance of about 1 mile from multiple sources.	NOA—baseline. No difference among alternatives: the MAR and accident conditions are unaffected by the alternatives.
SITE–03	Very large earthquake on the Pajarito Fault and perhaps the Embudo Fault, resulting in structural damage to essentially all facilities.	Approximately 7.1 x 10^{-5} per year (i.e., one such event in approximately 14,000 years).	Mean population dose approximately 210,758 person-rem, resulting in approximately 134 excess LCFs; MEI dose 247 rem; approximately 100 people exposed above ERPG–2 or ERPG–3 levels to a distance of about 1 mile from the sources.	NOA—baseline. No difference among alternatives; the MAR and accident conditions are unaffected by the alternatives.
SITE–03, Surface Rupture	Very large earthquake on the Pajarito Fault, resulting in structural damage to essentially all facilities with surface rupture possible on subsidiary faults.	Approximately 1 to 3 x 10^{-5} per year (i.e., one such event in 95,000 to 32,000 years).	Mean population dose approximately 344,581 person-rem, resulting in approximately 233 excess LCFs; MEI dose < 380 rem; approximately 100 people exposed above ERPG–2 or ERPG–3 levels to a distance of about 1 mile from multiple sources.	NOA—baseline. No difference among alternatives; the MAR and accident conditions are unaffected by the alternatives.
SITE–04	Site-wide wildfire consuming combustible structures and vegetation.	Approximately 0.1 per year (i.e., one every 10 years).	Mean population dose approximately 675 person-rem, resulting in approximately 0.34 excess LCFs; MEI dose < 25 rem; potential for limited exposure to chemicals.	NOA—baseline. No difference among alternatives; the MAR and accident conditions are unaffected by the alternatives.
CHEM–01	Large leak chlorine release (69 to 75 lb) from potable water treatment station due to human error during cylinder changeout or maintenance, or due to random hardware failures.	Approximately 1.2 x 10^{-3} per year (i.e., one such event in approximately 800 years).	For the risk-dominant large leak scenario, an average of approximately 43 people exposed above ERPG–2 levels, and approximately 12 people exposed above ERPG–3 levels to distances of up to a few tenths of 1 mile.	NOA—baseline. EXP—approximately 5% more likely. RED—approximately 5% less likely. GRN—same as baseline; no change in severity.

TABLE G.5–1.—*Summary of Consequences from Risk-Significant Accidents at LANL*[a]-Continued

SCENARIO	DESCRIPTION	BASELINE LIKELIHOOD[b]	BASELINE CONSEQUENCE MEASURES[c]	EFFECT OF ALTERNATIVES[d]
CHEM–02	Multiple cylinder release (1,500 lb) from toxic release gas storage shed at Gas Plant due to fire or aircraft crash.	Approximately 1.3×10^{-4} per year (i.e., one in approximately 8,000 years).	Average of 292 people within LANL (ranging from none to 1,000 depending upon wind direction) exposed at or above ERPG–2 or ERPG–3 levels; town protected by canyon from highest concentrations.	NOA—baseline. EXP—approximately 14% more likely. RED—approximately 5% less likely. GRN—same as baseline; no change in severity.
CHEM–03	Chlorine release (68 to 75 lb) from toxic gas storage shed at Gas Plant due to random failure or human errors during cylinder handling.	Approximately 1.2×10^{-4} per year (i.e., one in approximately 8,000 years).	An average of approximately 263 people exposed above ERPG–2 levels or 239 above ERPG–3 levels at distances to a fraction of 1 mile, all within LANL; town protected by canyon from highest concentrations.	NOA—baseline. No difference among alternatives; the MAR and accident conditions are unaffected by the alternatives.
CHEM–04	Bounding single container release of toxic gas (selenium hexafluoride) from waste cylinder storage.	Approximately 4.1×10^{-3} per year (i.e., one in approximately 250 years).	Average number of off-site people exposed above ERPG–2 level is zero; toxic effects generally limited to the source's technical area (TA–54).	NOA—baseline. No change in likelihood or severity among the alternatives.
CHEM–05	Bounding multiple cylinder release of toxic gas (sulfur dioxide) from waste cylinder storage.	Approximately 5.1×10^{-4} per year (i.e., one event in approximately 2,000 years).	Under conservative daytime conditions, no one outside the source area (TA–54) would see levels above ERPG–2. Under least favorable conditions, 13 people could be exposed above ERPG–3 levels and 59 above ERPG–2 levels.	NOA—baseline. No change in likelihood or severity among the alternatives.
CHEM–06	Chlorine gas release outside Plutonium Facility.	Approximately 6.3×10^{-2} per year (i.e., one event in approximately 16 years).	Average number of people exposed at or above ERPG–2 doses is approximately 102, and above ERPG–3, approximately 7 at ranges to a fraction of 1 mile.	NOA—baseline. No change in likelihood or severity among the alternatives.
RAD–01[e]	Plutonium release from RANT Facility transuranic waste container storage area fire.	Approximately 1.6×10^{-3} per year (i.e., one event in approximately 600 years).	Mean population dose approximately 72 person-rem, resulting in approximately 0.04 excess LCF; MEI dose at nearest public access (on Pajarito Road) approximately 46 rem; at most exposed residence approximately 4 rem.	NOA—baseline. No change in likelihood or severity among the alternatives.
RAD–02	Plutonium release from the CMR Building due to natural gas pipe-line break, gas ingestion into facility, and subsequent explosion and fire.	Negligible likelihood, $< 10^{-6}$ per year or > 1,000,000 years between occurrences.	Mean population dose approximately 120,000 person-rem, resulting in approximately 57 excess LCFs; MEI dose at nearest public access (Diamond Road) approximately 4000 rem; at nearest residence approximately 170 rem.	NOA—baseline. No change in likelihood or severity among the alternatives.

TABLE G.5–1.—*Summary of Consequences from Risk-Significant Accidents at LANL*[a]-Continued

SCENARIO	DESCRIPTION	BASELINE LIKELIHOOD[b]	BASELINE CONSEQUENCE MEASURES[c]	EFFECT OF ALTERNATIVES[d]
RAD–03	Highly enriched uranium release from power excursion accident with Godiva-IV outside Kiva #3.	Approximately 3.4 x 10^{-6} per year (i.e., one event in 300,000 years).	Mean population dose approximately 110 person-rem, resulting in approximately 0.06 excess LCF; MEI dose at nearest public access (Pajarito Road) approximately 150 rem; at nearest habitation approximately 0.5 rem.	NOA—baseline. EXP—approximately 25% more likely. RED and GRN—no change in likelihood. No change in severity among the alternatives.
RAD–04[f]	Inadvertent detonation of plutonium-containing assembly at DARHT firing point.	Negligible likelihood, < 10^{-6} per year or > 1,000,000 years between occurrences.	Mean population dose approximately 9,000 person-rem, resulting in approximately 5 excess LCFs; MEI dose for nearest public access (State Route 4) approximately 76 rem.	NOA—baseline. No change in likelihood or severity among the alternatives.
RAD–05	Tritium oxide release due to aircraft crash at TSFF.	5.3 x 10^{-6} per year (i.e., one accident in 190,000 years).	Mean population dose approximately 24 person-rem; 0.012 excess LCF or negligible chance of excess LCF. MEI approximately 0.01 rem.[g]	NOA—baseline. The same for all alternatives, except with RED, the tritium available for release is reduced by 25% in one but not both buildings.
RAD–06	Plutonium release due to aircraft crash at RAMROD.	Negligible likelihood, < 10^{-6} per year or > 1,000,000 years between occurrences.	Mean population dose approximately 7,900 person-rem, resulting in approximately 4 excess LCFs.	NOA—baseline. No change among alternatives.
RAD–07	Plutonium release from WCRRF transuranic waste container storage area fire.	1.5 x 10^{-4} per year (i.e., one in 7,000 years).	Mean population dose approximately 1,300 person-rem, resulting in approximately 0.7 excess LCF; MEI dose at closest public access (Pajarito Road) approximately 74 rem; at closest habitation approximately 4 rem.	NOA—baseline. EXP—likelihood doubles due to higher waste throughput. RED—likelihood reduced by 25%. GRN—same as baseline; no change in severity.
RAD–08	Plutonium release from TWISP transuranic waste storage domes due to aircraft crash and fire.	4.3 x 10^{-6} per year (i.e., one event in approximately 200,000 years).	Mean population dose approximately 400 person-rem, resulting in approximately 0.2 excess LCF; MEI dose at nearest public access (Pajarito Road and nearest border with White Rock) 22 rem.	NOA—baseline. No effect of alternatives on crash likelihood or maximum waste loading assumed in the analysis.

TABLE G.5–1.—*Summary of Consequences from Risk-Significant Accidents at LANL*[a]-Continued

SCENARIO	DESCRIPTION	BASELINE LIKELIHOOD[b]	BASELINE CONSEQUENCE MEASURES[c]	EFFECT OF ALTERNATIVES[d]
RAD–09	Plutonium release due to transuranic waste drum failure or puncture (for high and typical activity in drum).	4.1 x 10^{-3} per year (i.e., one in approximately 250 years for high-activity drum); 0.4 per year (i.e., 1 in 2.5 years for typical-activity drum).	Mean population dose (high-activity drum) approximately 230 person-rem, 0.12 excess LCF. Mean population dose (typical-activity drum) approximately 4.3 person-rem, with 0.0022 excess LCF or negligible risk. MEI dose of 0.41 rem.	NOA—baseline. Number of drum operations, and thus likelihood, up 20% for EXP; down 5% for RED. GRN—same as baseline.
RAD–10	Plutonium release from degraded storage container at plutonium facility.	< 10^{-6} per year; negligible likelihood of external release (i.e., < 10^{-6} per year).	For the incredible accident, mean population dose approximately 560 person-rem, with 0.28 excess LCF. MEI dose of approximately 44 rem at Pajarito Road boundary.	NOA—baseline. Alternatives do not alter the likelihood or severity of these accidents associated with the repackaging of stored plutonium.
RAD–11[f]	Container breach after detonation of plutonium-containing assembly at DARHT firing point.	Negligible likelihood, < 10^{-6} per year or > 1,000,000 years between occurrences.	Mean population dose approximately 210 person-rem, resulting in < 1 excess LCF; MEI dose (maximum dose point on State Route 4) approximately 14 rem.	NOA—baseline. Alternatives do not alter the likelihood or severity of such accidents.
RAD–12[f]	Explosively driven dispersal of plutonium at TA–16–411.	1.5 x 10^{-6} per year or about 1 in 670,000 years.	Mean population dose approximately 35,800 person-rem; 18 excess LCFs. MEI (maximum dose at closest site boundary) 138 rem.	NOA—baseline. Alternatives do not alter the likelihood or severity of such accidents.
RAD–13	Plutonium release from flux trap irradiation experiment at TA–18.	1.6 x 10^{-5} per year (i.e., one event in 62,000 years).	Mean population dose approximately 160 person-rem, resulting in 0.08 excess LCF; MEI dose at closest public access (Pajarito Road) is approximately 120 rem; at closest habitation is approximately 0.12 rem.	NOA—baseline. Alternatives do not alter the likelihood or severity of such accidents.
RAD–14	Plutonium release from ion exchange column thermal excursion at Plutonium Facility.	< 10^{-6} per year (i.e., < 1 in one million years).	Mean population dose approximately 130 person-rem (i.e., 0.063 excess LCF); MEI dose 0.45 rem at Pajarito Road and 0.32 rem at closest habitation.	NOA—baseline. Alternatives have no effect on likelihood or severity of such accidents.

TABLE G.5–1.—*Summary of Consequences from Risk-Significant Accidents at LANL*[a]-Continued

SCENARIO	DESCRIPTION	BASELINE LIKELIHOOD[b]	BASELINE CONSEQUENCE MEASURES[c]	EFFECT OF ALTERNATIVES[d]
RAD–15	Plutonium release from the ARIES process: (1) Hydride-dehydride glovebox fire. (2) Plutonium release from wing fire.	(1) 3.6 x 10^{-5} per year (2) 3.2 x 10^{-5} (i.e., 1 in about 30,000 years for both accident scenarios).	(1) Mean population dose 4.5 person-rem; approximately 0.0023 excess LCFs; MEI at closest public access: approximately 4.1 rem. (2) Mean population dose approximately 1,700 person-rem; approximately 0.85 excess LCFs, MEI at closest public access: approximately 91 rem.	NOA—baseline. EXP— (1) Increases the severity of the accident by approximately 4 times that of the NOA. (2) Increases the severity of the accident by approximately 100% over the NOA. RED and GRN—remain the same as the NOA. Frequencies remain the same across alternatives.
RAD–16[g]	Plutonium release due to aircraft crash at the CMR Building.	Approximately 3.5 x 10^{-6} per year (i.e., one event in approximately 300,000 years).	Mean population dose: approximately 56 person-rem; 0.03 excess LCFs expected; MEI dose at closest public access approximately 3 rem; at nearest habitation approximately 0.03 rem.	NOA—baseline. Alternatives do not alter the likelihood or severity of such accidents.
WORK–01	Inadvertent detonation of high explosives.	10^{-3} to 10^{-2} per year (i.e., one in approximately 100 to 1,000 years).	1 to 10 fatalities or injuries.	NOA—baseline. EXP—50% increase in likelihood. RED—20% reduction in likelihood. GRN—40% reduction in likelihood.
WORK–02	Biohazard contamination of a single worker.	10^{-2} to 10^{-1} per year (i.e., one in approximately 10 to 100 years).	One casualty.	NOA—baseline. No differences among alternatives apart from the addition of one more pathogen in EXP.
WORK–03	Inadvertent criticality event at the CMR Building, Critical Experiments Facility, or Plutonium Facility.	< 10^{-5} per year (i.e., one in more than 100,000 years).	Substantial doses to those few workers in the immediate vicinity, with possible fatalities from acute exposures.	NOA—baseline. Alternatives have little effect on likelihood and none on severity of such accidents.
WORK–04	Inadvertent exposure of workers to electromagnetic radiation.	10^{-2} to 10^{-1} per year (i.e., one in approximately 10 to 100 years).	Typically one, rarely several, casualties.	NOA—baseline. Alternatives have little effect on likelihood and none on severity of such accidents.

TABLE G.5–1.—*Summary of Consequences from Risk-Significant Accidents at LANL*[a]-Continued

SCENARIO	DESCRIPTION	BASELINE LIKELIHOOD[b]	BASELINE CONSEQUENCE MEASURES[c]	EFFECT OF ALTERNATIVES[d]
WORK–05	Plutonium release from degraded storage container at Plutonium Facility	0.23 per year (i.e., one in approximately 5 years).	Significant but nonlethal doses to one to two operators.	NOA—baseline. Alternative have little effect on likelihood and none on severity of such accidents.

[a] See the individual narratives for each accident in section G.5 for additional information.

[b] Accident likelihood estimates are conservative, given the information available. However, for the particularly unlikely accidents, it is possible that there are causal mechanisms that were missed; therefore, the possibility of a more probable scenario cannot be rigorously ruled out. The frequency per year is more correctly described as the probability of occurrence in any 12-month period. See detailed explanation under Meaning of Risk and Frequency in section G.1.

[c] Conservative assumptions have been employed in estimating the quantity and form of the hazardous materials available for release. Accident consequences are generally conservative (pessimistic) but do not bound the effects of accidents occurring under unusually unfavorable weather conditions. The results quoted for radiological accidents are weather-averaged. MEIs for each location are hypothetical individuals who do not leave and do not take protective actions to avoid exposure. Excess LCFs are cancers resulting from, and that develop well after, exposure to ionizing radiation. The excess LCF is the product of the dose and the risk factor of 5×10^{-4} excess LCF/person-rem. This is discussed in the primer on the effects of radiation in section D.1 of appendix D, Human Health.

[d] Explanations of the alternatives: No Action (NOA), Expanded Operations (EXP), Reduced Operations (RED), and Greener (GRN) appear in the introduction to this appendix and in chapter 3. The baseline risk is the risk from current operations, plus planned activities. Together, these constitute the NOA. There is frequently no difference among the alternatives in accident frequency and public consequence. The inventories used in the analyses are typically those of bounding permitted or administrative limits, rather than realistic values that would be more likely to change among the alternatives. The accident frequencies depend upon the accident initiators, many of which are independent of the operations and of inventory, and therefore, do not change among alternatives. Frequencies that depend upon operations, such as the number of drums being processed, do not necessarily translate into change in frequency of an environmental release, but may affect the frequency of worker accidents.

[e] As with other plutonium doses, these 4,000 rem are the total dose that accumulates over a 50-year lifetime as a result of the initial intake.

[f] These accidents are taken from the DARHT EIS (DOE 1995a) and utilize different modeling from the others shown in this table; therefore, the results may not be strictly comparable. For example, the integrated exposures for these accidents do not include exposures to on-site workers. The DARHT EIS treated the on-site workers as noninvolved workers. The doses were given as an individual dose and not included in the integrated population numbers. For this reason, integrated population doses in this EIS are higher than those in the DARHT EIS; however, both EISs assessed the consequences to noninvolved workers. See text under each accident for elaboration.

[g] This is at 360-meter distance. The closest public access would likely be involved in the crash.

TABLE G.5.1–1.—*Summary of Consequences to Workers at Accident Origination Facilities*

SCENARIO	DESCRIPTION	FACILITY WORKER CONSEQUENCES
SITE–01	Moderate earthquake on the Pajarito Fault or a large earthquake in the Rio Grande Rift zone, resulting in structural damage and/or severe internal damage to comparatively low-capacity facilities.	Workers in buildings that are structurally damaged or that suffer partial or total collapse (unusual, but possible) could be injured or killed. Worldwide experience with very severe earthquakes indicates that *a priori* predictions of the numbers of injuries and fatalities are not possible. The experience clearly indicates that large numbers of fatalities (i.e., many hundreds to thousands of deaths) are not commonly experienced except under special conditions. These special conditions include severe earthquakes with large numbers of people in severely substandard structures that suffer complete collapse. Modern structures do not often experience such failures, even in very severe earthquakes. Other circumstances under which large numbers of fatalities can occur include seismically induced, widespread fires. Other impacts to workers can include delayed emergency response (including medical assistance) and indirect effects from releases of hazardous materials (both inside facilities and to the environment).
SITE–02	Large earthquake on the Pajarito Fault, resulting in structural damage and/or severe internal damage to comparatively moderate-capacity facilities.	See SITE–01.
SITE–03	Very large earthquake on the Pajarito Fault and perhaps the Embudo Fault, resulting in structural damage to essentially all facilities.	See SITE–01.
SITE–04	Site-wide wildfire consuming combustible structures and vegetation.	All threatened workers would be evacuated prior to arrival of the fire front. Aircraft crashes have occurred while dropping slurry on wildfires. Firefighters are at risk if they enter an area without an alternate escape route, and there have been historical fatalities from such events. However, because life safety is given first priority over protection of property at LANL, it is not likely that there will be worker fatalities. Some firefighters and other emergency personnel are likely to have significant but transient effects from smoke inhalation.
CHEM–01	Chlorine release (up to 150 pounds) from potable water treatment station due to human error during cylinder changeout or maintenance, or due to random hardware failures.	For the cylinder rupture event, it is unlikely that workers will be present because due to the nature of the event, it is assumed to occur at random rather than as a result of worker activity. Even with very prompt response by workers inside the building when the release occurs, severe injury or fatality is possible with large chlorine leak rates. The number of injuries and fatalities depends on the exact number and location of workers at the facility at the time of the event. For small leak rates, the likelihood of injury or death is low due to the self-annunciating nature of the event.

TABLE G.5.1–1.—*Summary of Consequences to Workers at Accident Origination Facilities*-Continued

SCENARIO	DESCRIPTION	FACILITY WORKER CONSEQUENCES
CHEM–02	Multiple-cylinder release (1,500 pounds) from toxic gas storage shed at Gas Plant due to fire or aircraft crash.	Workers present at the Gas Plant (TA–3–170 and environs) can be injured or killed, depending upon wind direction and wind speed. However, the chlorine gas and fire causing the release will be readily visible, and escape from the plume, even on foot, is likely. Workers attempting to fight the fire without personal protective equipment can be overcome by chlorine gas.
CHEM–03	Chlorine release (150 pounds) from toxic gas storage shed at Gas Plant due to random cylinder failure or multiple human errors during cylinder handling.	Gas Plant workers who are directly involved in handling the cylinders of chlorine can be exposed to ERPG–2 or ERPG–3 concentrations from the human error contributor to this event. In the case of random failures, it is unlikely that workers will be in the immediate vicinity of the cylinder. Gas Plant workers can be exposed to high concentrations of chlorine if located outdoors; but these employees will be able to evacuate the area rapidly, which would tend to reduce exposure consequences.
CHEM–04	Bounding single-cylinder release of toxic gas (selenium hexafluoride) from waste cylinder storage.	There are typically four or five employees in the area during normal work hours. Injuries or fatalities can occur due to exposures as well as missiles from cylinder rupture. Workers are trained to leave the area in the event of a gas release. Consequences will depend on wind speed and direction.
CHEM–05	Bounding multiple-cylinder release of toxic gas (sulfur dioxide) from waste cylinder storage.	See CHEM–04.
CHEM–06	Chlorine release outside Plutonium Facility.	Air intakes at TA–55–4 are on the west end of the building, about 18 feet (5 meters) above the ground, and the chlorine release location is on the north side of the building at ground level. In addition, there is an isolation valve in the intake ductwork. Thus, it is unlikely that chlorine will be drawn into the building. Personnel located outdoors can be exposed to ERPG–2 and ERPG–3 concentrations of chlorine; but these employees will be able to evacuate the area rapidly, which would tend to reduce exposure consequences.
RAD–01	Plutonium release from RANT Facility transuranic waste container storage area fire.	There are about a dozen employees at the facility during day shift who can be at risk of plutonium inhalation as a result of this fire. However, the employees would be expected to take shelter or evacuate the area, which would reduce exposures. No lethal exposures would be expected.
RAD–02	Plutonium release from the CMR Building due to natural gas pipeline break, gas ingestion into facility, and subsequent explosion and fire.	Workers in the wing affected by the explosion can be severely injured or killed due to the dynamics of the explosion and the subsequent fire. Workers not directly affected by the explosion can inhale airborne plutonium that results from the explosion and subsequent fire. Contaminated air can be drawn into the building and dispersed to otherwise unaffected wings of the building.

TABLE G.5.1–1.—*Summary of Consequences to Workers at Accident Origination Facilities*-Continued

SCENARIO	DESCRIPTION	FACILITY WORKER CONSEQUENCES
RAD–03	Highly enriched uranium release from power excursion accident with Godiva-IV outside Kiva #3.	Personnel will not be located outdoors during an experiment leading to this accident. The TA–18 control building provides 40% attenuation of gamma radiation; ventilation systems will be secured in the event of an accident, minimizing the air exchange rate with the outdoors. No acute fatalities are expected for this accident.
RAD–04	Inadvertent detonation of plutonium-containing assembly at DARHT firing point.	Up to15 fatalities can occur among workers directly affected by blast effects. Other workers farther away can be injured and/or exposed to airborne radioactivity (the latter depends on wind speed and direction and the location of the workers). Workers not directly affected by the blast could receive nonlethal exposures of up to 160 rem at 1,300 feet (400 meters) and up to 90 rem at 2,430 feet (750 meters).
RAD–05	Tritium oxide release due to aircraft crash at TSFF or TSTA.	An aircraft crash into the building can result in severe injuries or deaths to nearly all the occupants of the building. Nearby workers not within the facility can also be injured or killed as a result of the crash dynamics, explosion, fire, missiles, etc. Workers not directly affected by the aircraft crash can be exposed to tritium oxide, but the release plume will be elevated and may skip over the immediate crash site before returning to the ground at some distance.
RAD–06	Plutonium release due to aircraft crash at RAMROD.	An aircraft crash into the building can result in severe injuries or deaths to nearly all the occupants of the building. Nearby workers not within the facility can also be injured or killed as a result of the crash dynamics, explosion, fire, missiles, etc. Workers not directly affected by the aircraft crash could be exposed to plutonium, but the release plume will be elevated and may skip over the immediate crash site before returning to the ground at some distance. (Note that this scenario was found, after detailed analysis, to screen on a frequency less than 1×10^{-7} per year.)
RAD–07	Plutonium release from WCRRF transuranic waste container storage area fire.	There are typically five WCRRF workers present during normal operations. The postulated accident will not result in an immediate release, providing time for implementation of evacuation or other protective measures. No fatal exposures are expected.
RAD–08	Plutonium release from TWISP transuranic waste storage domes due to aircraft crash and fire.	A small number of workers may be present during normal operations and can be directly affected by crash dynamics, explosion, fire, missiles, etc. Workers not directly affected by the aircraft crash can be exposed to plutonium, but the release plume will be elevated and may skip over the immediate crash site before returning to the ground at some distance.

TABLE G.5.1–1.—*Summary of Consequences to Workers at Accident Origination Facilities*-Continued

SCENARIO	DESCRIPTION	FACILITY WORKER CONSEQUENCES
RAD–09	Plutonium release due to transuranic waste drum failure or puncture.	The accident results in an immediate dispersal of plutonium to the area where the work is being performed. The dose to the worker will be dependent on ambient conditions and the speed with which protective actions can be taken (e.g., evacuation). No acute fatalities are expected for this accident.
RAD–10	Plutonium release from degraded storage container at Plutonium Facility.	The workers present when a container fails could be exposed to plutonium inhalation with substantial doses possible, depending upon the usage of PPE and the speed with which workers exit the immediate area.
RAD–11	Container breach after detonation of plutonium-containing assembly at DARHT firing point.	No fatalities are expected for the containment failure event because workers will be inside the facility and protected from material releases. Workers not directly involved with the experiment can receive nonlethal doses of up to 60 rem at 1,300 feet (400 meters) and up to 20 rem at 2,460 feet (1,750 meters).
RAD–12	Plutonium release from seismically initiated event at TA–16–411.	Workers within the facility would be killed by the explosion and building collapse.
RAD–13	Plutonium release from flux trap irradiation experiment at TA–18.	See RAD–03.
RAD–14	Plutonium release from ion exchange column thermal excursion at Plutonium Facility.	Workers in the room where the event occurs can be injured or killed due to the dynamics of the accident. Plutonium particulate inhalation is also possible. No fatalities have occurred in past resin thermal excursion events at other facilities.
RAD–15	Plutonium release from hydride-dehydride glovebox fire.	From one to three workers may be present attending the operations. These workers can be killed or injured due to the direct effects of a laboratory fire or can be exposed to plutonium particulates via inhalation. Other workers can be affected by smoke inhalation. Workers outside the facility will not be expected to be impacted due to redundant trains of HEPA filtration between the accident location and the outside environment.
RAD–16	Plutonium release due to aircraft crash at the CMR Building.	An aircraft crash into the CMR Building can result in severe injuries or deaths to nearly all the occupants of the building. Nearby workers not within the facility can also be injured or killed as a result of the crash dynamics, explosion, fire, missiles, etc. Workers not directly affected by the aircraft crash can be exposed to plutonium, but the release plume will be elevated and may skip over the immediate crash site before returning to the ground at some distance.
WORK–01	Inadvertent detonation of high explosives.	One to several workers can be killed due to explosion dynamics. The actual number of workers depends on the circumstances of the explosion (e.g., type of activity in progress, quantity of explosives involved, distances of workers from explosion site, etc.).

TABLE G.5.1–1.—*Summary of Consequences to Workers at Accident Origination Facilities*-Continued

SCENARIO	DESCRIPTION	FACILITY WORKER CONSEQUENCES
WORK–02	Biohazard contamination of a single worker.	One worker can be contaminated by this accident. The outcome of the contamination depends on the nature of the agent involved and the extent and efficacy of medical intervention. Fatality is possible but not likely, based on experience in the medical and research communities.
WORK–03	Inadvertent criticality event at the CMR Building, Critical Experiments Facility, or Plutonium Facility.	One or more workers can be killed due to acute radiation exposure, but the lethal zone is limited to tens of meters from the site of the criticality event. Other workers can receive sublethal exposures or can inhale fission products.
WORK–04	Inadvertent exposure of workers to electromagnetic radiation.	Severe injury or death is possible in the worst case. Sublethal effects (e.g., eye injuries) are also possible.
WORK–05	Plutonium release from degraded storage container at Plutonium Facility.	The workers handling the container can be exposed to plutonium particulates by inhalation. Significant but nonlethal doses are possible depending on the usage of personal protective equipment and the speed with which the workers exit the immediate area.

G.5.3 Note on the Consequences from Earthquakes

For the site-wide earthquakes, the earthquake frequency, the MAR (dominant contributors), and accident consequences across the alternatives are also projected to be comparable.

G.5.4 Site-Wide Earthquake and Wildfire Accidents

LANL is located within the Rio Grande Rift, a tectonically active province in the western U.S. Although only six historic earthquakes of Richter magnitude (ML) of 5.0 or greater have occurred in the LANL region, the period of historical observation is short (from about 1850 for events of ML 5.5) (Wong et al. 1995). Although no surface faulting has occurred in historic times, detailed paleoseismic investigations have found evidence of surface faulting in prehistoric times. Seismic studies currently in progress have further evaluated the potential for ground faulting. These studies indicate the possibility of such events is low, but credible, at some locations on the LANL site. Section 4.2.2.2 (in volume I, chapter 4) and appendix I further discuss the recently completed studies and their implication to DOE and LANL.

In order to evaluate the seismic hazards at LANL more fully, and in accordance with the guidance contained in DOE Standards 1020 and 1023 (DOE 1994e and DOE 1995b), LANL contracted with Woodward-Clyde Federal Services to perform a state-of-the-art PSHA. PSHA provides estimates of the frequency of various levels of ground movement (e.g., peak horizontal ground acceleration [PGA], represented in terms of the multiple of the force of gravity, represented by the letter "*g*"). The analysis evaluated the contribution of 25 faults to the seismic hazard at LANL, accounting for all known faults within 93 miles (150 kilometers) of the site that could produce ground accelerations of 0.05 *g* or greater (e.g., a PGA of 0.05 *g* is representative of the onset of strong ground shaking) (Wong et al. 1995). In addition, areal seismic sources were considered in an attempt to account for hidden faults that could produce earthquakes of up to magnitude 6.5 (larger faults would produce surface ruptures that would be represented already).

The Woodward-Clyde analysis found that most of the seismic hazard at LANL is due to projected seismic activity in the Rio Grande Rift and along the Pajarito, Rendija Canyon, Guaje, Sawyer Canyon, and Embudo faults. The surface expression of the Pajarito fault runs along the western boundary of LANL. The fault, which is a down-to-the-east fault, underlies the entire laboratory; all significant facilities at LANL are within 3.5 miles (5.6 kilometers) of the surface expression of the fault. The two facilities with the largest radiological hazard potential at LANL are the CMR Building and TA–55–4 facility, which are 0.4 and 1.9 miles (0.7 and 3.1 kilometers), respectively, from the surface expression of the Pajarito Fault. Therefore, the structures at LANL are considered to be near-field for the purposes of an earthquake along the Pajarito Fault. This near-field status means that large vertical displacements could occur in an earthquake along the Pajarito Fault, along with the horizontal displacements. Modeling performed by Woodward-Clyde indicates that vertical accelerations could exceed the horizontal acceleration at near-source distances of up to 6 miles (10 kilometers).

PSHA for Los Alamos indicates that the frequency of a very large peak horizontal ground acceleration (1.0 *g*) is approximately one in one hundred thousand per year, or 1.0×10^{-5} per year. Because the most structurally robust facility at LANL has a design basis earthquake of 0.31 *g*, it is clear that earthquakes have a potential to cause significant damage to LANL facilities.

The risks posed by earthquakes at LANL have been assessed on a site-wide basis, unlike existing safety documentation, which considers the facilities independently. The seismic analysis herein is based on PSHA, on available safety documentation (which in many cases provides information on the seismic capacity of important structures), on facility walkdowns conducted by the SWEIS accident analysts, and on engineering judgment. The approach taken in the analysis was to estimate conservative structural failure thresholds (referred to as HCLPF values), which correspond roughly to a high confidence that the conditional probability of structural failure is 5 percent or less at a given ground acceleration. By estimating conservative HCLPF values, the frequency of failure can be established with greater confidence than if the median or mean fragility values were estimated using limited resources. This approach places most of the uncertainty in failure frequency on the down side of the risk estimates; that is, it is much more likely that the actual failure frequency is lower than the estimated value than it is higher. Still, with a consistent approach to the analysis, the relative ranking of seismically initiated failures should be valid.

Once the HCLPF values are estimated (these values are tabulated in Table G.5.4–1), the seismic hazard information can be convolved with the HCLPF values to calculate the failure frequency. Because the seismic hazard is not very different among the eight LANL sites analyzed, the seismic hazard from TA–55 was used in quantification. The frequency of failure corresponding to HCLPF values for TA–55 is presented in Table G.5.4–2. Using the information in Tables G.5.4–1 and G.5.4–2, seismic failure events and their corresponding frequencies of occurrence were estimated as set forth in Table G.5.4–3.

In principle, if the assessment of seismically initiated accidents was being done as part of a full-scope PRA, the frequency of structural failure (or internal component/system damage) could be calculated uniquely for each structure and risks calculated separately for each resulting chemical or radiological release. However, the SWEIS accident analysis is not a seismic PRA. The goal of the analysis is to identify for the decision maker and stakeholders the risks associated with the SWEIS alternatives and to evaluate whether there are any significant differences in accident risks across the alternatives. Examining the results of the analysis in Table G.5.4–3, and considering the approximate method by which the HCLPF values were assigned, the uncertainties in the results are such that grouping the failure events by frequencies within a factor of three or four of one another is not unreasonable. Based on Table G.5.4–3, three site-wide earthquakes were identified, as listed in Table G.5.4–4. In addition, the potential impact of ground faulting at one facility of concern, the CMR Building, will be discussed as a subsection of the SITE–03 event.

Appendix I summarizes the ongoing and recently completed seismic hazard studies, as well as the implications of these studies for DOE and LANL. The uncertainties in the estimated seismic risk are large. The seismic hazard estimate alone has significant uncertainties. To illustrate, the uncertainties in the seismic hazard are such that the 5^{th} to 95^{th} percentile horizontal PGA values at a frequency of 1×10^{-5} per year range from about 0.55 *g* to much greater than 1.0 *g*. Similarly, the 5^{th} to 95^{th} percentile frequency values, for a horizontal PGA of 1.0 *g*, spans the range from 5×10^{-5} to much less than 1×10^{-6} per year.

G.5.4.1 *SITE–01, Site-Wide Earthquake Causing Damage to Low-Capacity Structures/Internals*

Consequences of SITE–01 for Facility Workers and the Public

The consequences of SITE–01 are presented separately for workers and the public. For

TABLE G.5.4–1.—*Estimated High Confidence in Low Probability of Failure Capacities of LANL Structures and Internals*

FACILITY DESIGNATION	FAILURE HCLPF[a]	NOTES
TA–00–1109	0.04	Unreinforced concrete block structure; large-diameter natural gas pipeline and pumping station located within 50 feet of this structure; a small-diameter natural gas pipe also enters the structure; HCLPF based on judgment and Campbell et al. 1988.
TA–00–1110	0.04	Unreinforced concrete block structure; two large water tanks located within 100 feet of this structure; HCLPF based on judgment and Campbell et al. 1988.
TA–3 Admin. Complex	0.04	0.15 *g* PGA calculated as having a high probability of failure (Miller et al. 1995); also consistent with LANL 1991a.
TA–3–29 (CMR)	0.08	The CMR Building expected to fail at 0.17 *g* median fragility (LANL 1995c), corresponding to a HCLPF of 0.08 *g*. The basement vault is expected to survive intact, but may suffer damage and leakage at earthquake magnitudes comparable to a HCLPF of 0.34 *g* (frequency of 7.1 x 10^{-5}/yr.).
TA–3–66 (Sigma)	0.05	Built in late 1950's; HCLPF based on LANL 1991a (original seismic design for 0.05 *g*) and PC 1996b (3 of 4 building sectors fail Federal Emergency Management Agency [FEMA] 178 life safety requirements corresponding to 0.14 *g* PGA).
TA–3–476	0.25	Judgmental estimate for overturning the shed in an earthquake.
TA–9–21	0.04	Judgmental estimate based on facility walkdown.
TA–15 DARHT	NA	No credible accident scenarios were identified wherein a seismic event could trigger a release from DARHT that would have any off-site impacts (DOE 1995a). If an earthquake were to occur with an assembly loaded and the containment sealed, not only would the container supports have to fail, but the explosives in the assembly would have to detonate and the containment would have to fail in order for a release to the environment to occur. The congruence of a sufficiently large earthquake, the conditional probability of an assembly being installed in the containment, the explosives detonating, and the containment structurally failing are considered to be incredible.
TA–16–205 (WETF)	0.14	Corresponds to 5 x 10^{-4}/yr frequency estimate in SAR based on Table G.5.1–2; this earthquake does not cause structural failure (LANL 1996e), but results in a tritium release due to failures internal to the facility coupled with failure of the ventilation isolation system (100 grams tritium oxide; 250 grams in the Expanded Operations Alternative).
	0.30	SAR estimates structural failure at 0.6 g (LANL 1996e); however, the frequency in the SAR (1.5 x 10^{-5}/yr) corresponds to an HCLPF of about 0.53 *g*, for which the median fragility would be much higher than 0.6 *g*. Indeed, that SAR frequency corresponds to approximately a 1.0 *g* PGA earthquake; the value shown here is a judgment pending further evaluation. In addition, during drafting of this SWEIS, DOE was informed that a seismically related unidentified safety question is in progress for WETF, which may lower the structural failure fragility to 0.3 *g*.
TA–16–411	0.05	Built in early 1950's; HCLPF based on judgment and PC 1996b (fails FEMA 178 life safety requirements corresponding to 0.14 *g* PGA).

TABLE G.5.4–1.—*Estimated High Confidence in Low Probability of Failure Capacities of LANL Structures and Internals*-Continued

FACILITY DESIGNATION	FAILURE HCLPF[a]	NOTES
TA–18–23 (Kiva #1)	0.05	Built in late 1940's to UBC criteria; HCLPF based on judgment and PC 1996b (fails FEMA 178 life safety requirements corresponding to 0.14 *g* PGA). Also calculated to be incapable of surviving the design basis earthquake of 0.22 *g* (LANL 1996f).
TA–18–32 (Kiva #2)	0.22	Analyzed in the SAR using finite element analysis against University of California Research Laboratory (UCRL–15910) seismic criteria and found to survive the design basis earthquake for a Hazard Category 2 facility. Assuming facility is DOE Standard 1020-94 Performance Category 2, HCLPF judgmentally assigned at 0.22 *g*, which corresponds to the Performance Category 2 earthquake at TA–18 (Wong et al.1995).
TA–18–116 (Kiva #3)	0.22	See notes for TA–18–32, above.
TA–18–168 (SHEBA)	0.22	See notes for TA–18–32, above.
TA–21–155 (TSTA)	0.10	Built in early 1950's; SAR indicates 0.33 *g* median fragility (LANL 1996g), but PC 1996b indicates that both sectors of building fail the FEMA 178 life safety requirements, corresponding to 0.14 *g* PGA. Building brought up to 1976 UBC requirements for seismic and wind; but the upgrade was not meant to conform to UCRL–15910 or DOE Standard 1020 (LANL 1996g).
TA–21–209 (TSFF)	0.10	Built in late 1960's; HCLPF based on SAR (LANL 1996h) and PC 1996b (all three sectors failed FEMA 178 life safety requirements, corresponding to 0.14 *g* PGA).
TA–43–1 (HRL)	0.08	HCLPF based on LANL 1991a (capable of 0.18 *g* resistance); 5 of 6 sectors failed FEMA 178 life safety requirements, corresponding to 0.14 *g* PGA (PC 1996b).
TA–50–1 Radioactive Liquid Waste Treatment Facility (RLWTF)	0.10	SAR states that the facility cannot withstand the 0.22 *g* design basis earthquake for a Performance Category 2 facility (LANL 1995d); HCLPF assigned by judgment based on SAR-reported frequency of 1.4 x 10^{-3}/yr (LANL 1995d).
TA–50–37 (RAMROD)	0.07	HCLPF assigned based on fragility of 0.15 *g* and corresponding frequency of 2 x 10^{-3}/yr (LANL 1996i).
TA–50–69 (WCCR Facility)	0.22	HCLPF assigned based on design basis earthquake of 0.22 *g* (LANL 1995e).
TA–54 TRU Domes	0.11	HCLPF assigned based on design basis earthquake of 0.22 *g* with a corresponding frequency of 1 x 10^{-3}/yr (LANL 1995f); corresponds to structural collapse of the tension dome structures of four domes and impact of 10% of the TRU waste drums on the top row of the stacks.
	0.31	HCLPF assigned based on beyond design basis earthquake of 0.57 *g* with a corresponding frequency of 1 x 10^{-4}/yr (LANL 1995f); corresponds to dome failure plus overturning of 10% of the TRU waste drums.
TA–54–38 (RANT)	0.11	HCLPF assigned based on the SAR, which states that the facility was designed to withstand seismic Zone 2 earthquake loads and design live loads per UBC 1985, corresponding to a 0.11 *g* design basis earthquake. However, additional bracing (tying together the roof and walls to resist the 100-year wind) brings the seismic resistance to greater than 0.11 *g* but less than the required 0.22 *g* for the facility (LANL 1996j).

TABLE G.5.4–1.—*Estimated High Confidence in Low Probability of Failure Capacities of LANL Structures and Internals*-Continued

FACILITY DESIGNATION	FAILURE HCLPF[a]	NOTES
TA–55–4	0.14	Design basis earthquake; facility structure remains intact, but some process enclosures collapse due to anchorage failure resulting in a free-fall spill of MAR and the rupture of process gas lines. Ventilation system fails due to loss of off-site power and failure of nonsafety-class ductwork within the building. LPF = 6% due to ventilation system failure and pressurized gas-driven release; frequency of this scenario is 4 x 10^{-4}/yr (LANL 1996k). The release for this scenario, calculated on a spreadsheet basis, is estimated at 1.16 x 10^{-2} grams of heat source plutonium, 5.17 grams of weapons-grade plutonium, 0.201 grams of plutonium-242, and 0.241 grams of highly enriched uranium (LANL 1996k).
	0.23	Beyond evaluation basis earthquake included in the SAR; similar to 0.30 *g* in that the structure remains intact with an LPF = 0.06, but more gloveboxes, etc., fail, increasing the source term. Release, calculated on a spreadsheet basis, is estimated at 1.74 x 10^{-2} grams of heat source plutonium, 5.31 grams of weapons-grade plutonium, 0.201 grams of plutonium-242, and 0.242 grams of highly enriched uranium (LANL 1996k).
	0.44	Beyond design basis earthquake not included in the TA–55 SAR; the structure has an HCLPF of 0.44 *g*, corresponding to an annual frequency of 3.16 x 10^{-5}/yr (LANL 1996k).
TA–55–185	0.31	TA–55–185 is a prefabricated metal building located on a concrete pad; it is a general use facility constructed in accordance with the 1988 UBC (DOE 1996g). HCLPF assigned based on judgment considering design and considering TA–54 Area G analysis for toppling of top row of TRU drums (LANL 1995f).
TA–55–249	0.23	Based on beyond evaluation basis earthquake for TA–55–4 (see above).

[a] Failure HCLPF is the ground acceleration where the probability of structural failure is 5% or less.

TABLE G.5.4–4.—*Identified Site-Wide Earthquakes*[a]

FREQUENCY RANGE/YR	POINT ESTIMATE FREQUENCY	CHARACTERIZATION OF EARTHQUAKE
SITE–01 1.1 x 10^{-3} to 4.7 x 10^{-3}	2.9 x 10^{-3}	Low capacity structures or internals fail
SITE–02 1.8 x 10^{-4} to 6.9 x 10^{-4}	4.4 x 10^{-4}	Moderate capacity structures or internals fail
SITE–03 3.2 x 10^{-5} to 1.1 x 10^{-4}	7.1 x 10^{-5}	Comparatively high capacity structures fail

[a] Based on the information provided in Table G.5.1–3.

workers, the following consequences are identified:

- Any time a facility occupied by workers is subjected to structural damage or collapse in an earthquake, injuries will occur and the potential for fatalities is also present. Worldwide experience with very severe earthquakes indicates that *a priori* predictions of the numbers of injuries and fatalities are not possible. The experience clearly indicates that large numbers of fatalities (i.e., many hundreds to thousands of deaths) are not commonly experienced except under special conditions. These special conditions include severe earthquakes with large numbers of people in severely substandard structures that suffer complete collapse. Modern structures do not often experience such failures, even in very severe earthquakes. Other circumstances under which large numbers of fatalities occur include seismically induced dam failures and seismically induced, widespread fires.
- Workers trapped in nonhazardous buildings could be exposed to radioactivity and chemicals released into the atmosphere as a result of structural damage to other facilities and fires.
- Medical assistance to injured workers could be delayed due to limited availability of immediate medical response resources as well as by damage to transportation routes (e.g., due to landslides or collapsed bridges).
- These same considerations also apply to the off-site public.

Under the SITE–01 earthquake scenario, LANL nuclear facilities, except for the CMR Building, and most of LANL nonnuclear facilities would not collapse. The general effect is the potential to spill, create a small fire, or otherwise cause limited damage to material. Material that is "in process" is more likely to experience this type of effect. As a conservative value, the wing or building limits have been used as the MAR in these accidents with all of this material subject to spills, free-fall impacts, and a limited amount involved in fires. Bounding values were used in determining the amount of this material that had the potential for airborne transport. If internal systems could be damaged, the LPF for the facility was assumed to be 1.0. (That is, given the occurrence of the earthquake, it is assumed that the facilities that would experience structural or systems damage would always do so in a manner that creates an unconstrained path for material release outside of the structure.) This is a very conservative assumption because such damage could also occur in a manner that does not result in the release of material outside of the structure. (For example, walls might crack, but material storage containers could remain intact, or only spill material within the structure.) For buildings that would not sustain internal structural or systems damage, the LPF was assumed to be zero.

As a specific example, in evaluating the impact of hypothesized building damage from a SITE–01 earthquake affecting the CMR Building, it was assumed that the full amount of the MAR (the wing limits) were in powder form, uncontained and unprotected, subject to impacts and spills from the earthquake ground motion and falling objects. All of this material was assumed to be freely available for dispersal to the outside following the building damage. For comparison, generally only about 40 percent of the material in the CMR Building is in powder form, the remainder being in metal or solution, and most of the materials are in storage containers during routine operations (most is not “in process”). Such storage containers would have to be breached in the course of or following the earthquake to make that material available for release. Thus, while there is a variety of scenarios that could be developed for the events resulting from such an earthquake, this approach represents a conservative case for the purposes of NEPA.

LANL nuclear facilities do meet the requirements for design basis earthquakes. This includes engineered controls to minimize the damage to internal structures and systems. However, for the purposes of NEPA, the seismic hazard is treated very conservatively. This approach is taken in recognition that the frequency and magnitude of earthquakes are uncertain. The uncertainty will remain until much more is known and understood about the causes of earthquakes and their effects, including the predictability of earthquake magnitudes for a given area. Far less uncertain is the response of buildings to given forces; however, the process for determining the exact values for building responses is both expensive and time consuming. For the purposes of this SWEIS and consistent with the requirements of NEPA, the analyses considered conservative values for both the amount of material that could be affected in these scenarios and the ability for facilities and their systems to contain hazardous material.

Based on the foregoing discussion and analysis, low capacity structures/internals subject to damage and resulting in radiological releases for a 2.9 x 10^{-3} annual frequency earthquake include TA–3–29 (CMR Building structural collapse), TA–18–23 (Kiva #1 structural failure), TA–21–155 (TSTA Facility structural failure), TA–21–209 (Tritium Science and Fabrication Facility structural failure), TA–50–1 (RLWTF structural failure), TA–50–37 (Radioactive Materials Research, Operations, and Demonstration Facility structural failure), TA–54 Area G (TWISP Storage Dome failure), and TA–54–38 (Nondestructive Assay and Nondestructive Examination Facility structural failure). The dominant MAR and source terms are associated with TA–3–29, TA–50–1, TA–50–37, TA–54 Area G, and TA–54–38. Note that facilities that pose small additional risk were not included in the analyses. An example is TA–16–411, where the MAR is in a very strong part of the structure (vault) and is there only part of the time, so that a release from this facility as a result of an earthquake is believed to border on the incredible. The probability of such a release is discussed in detail under section G.5.6.12, RAD–12.

Note that these analyses (SITE–01, SITE–02, and SITE–03) do not attempt to evaluate the effect upon the population from the earthquake itself. Certainly, an earthquake in the Los Alamos area would have broader implications upon the local community than just the damage to LANL facilities. The population effects discussed here would only be incremental to the significant damage sustained from the earthquake itself.

The mean collective population dose from the dominant source term contributors is projected to total about 27,726 person-rem total effective dose equivalent (TEDE), resulting in approximately 16 excess LCFs. Some 97 percent of the exposure rises from the CMR Building (TA–3–29), RAMROD (TA–50–37), and the RLWTF (TA–50–1). No acute (immediate) fatalities from radiation are expected to result from the earthquake event.

Doses to the MEI member of the public from the subject facilities will generally not be additive because of the diverse locations of the facilities and the attendant requirement that different wind directions at each facility converging on the MEI would be necessary to obtain concurrent exposures (not physically possible). MEI doses for community residents and the corresponding release sources are summarized as follows: (1) 20.2 rem (TEDE), Los Alamos townsite resident (TA–3–29); (2) 20.1 rem (TEDE), Royal Crest Trailer Park resident (TA–3–29, TA–50–1, TA–50–37); and (3) 3.0 rem (TEDE), White Rock resident (TA–54 Area G).

Chemical release consequences also have been calculated. Chemical releases include 300 pounds of chlorine released from TA–00–1109 and TA–00–1110, 7.6 liters of hydrogen cyanide produced by collapse of the floor at the Sigma facility (TA–3–66), 3 pounds of phosgene released from collapse of TA–9–21 (a laboratory building), and 30 liters of formaldehyde released from the Health Research Laboratory (TA–43–1). The consequences of these releases are described below (note that no emergency response actions are assumed, with exposure assessed as though the people exposed are located outdoors; both assumptions are conservative).

- *TA–00–1109 and TA–00–1110, 300 pounds chlorine released at each.* In both cases, the most likely outcome would be that the higher concentrations of chlorine (being a heavy gas) would proceed down into nearby canyons, and exposures to the public would be reduced. Under typical meteorological conditions, and assuming flat terrain for the sake of conservatism, the ERPG–3 concentration of 20 parts per million could be exceeded to a distance of 361 yards (330 meters). Concentration profiles at 200 and 300 yards (183 and 275 meters) show that the ERPG–3 value is exceeded for a little over 10 minutes for a person located outdoors. At a 100-yard (92-meter) distance, the ERPG–3 value is exceeded significantly, with an exposure of about 200 parts per million lasting for about 10 minutes outdoors (see properties of chlorine gas under CHEM–02). Indoors, these values would be less, but the increment is not known due to damage to structures (with an intact single-story structure, the indoors concentration at 328 yards [100 meters] does not exceed ERPG–3, with a maximum concentration of 13.5 parts per million calculated). The circumstances of the release are such that the total release would be less than 300 pounds. The failure mode is evaluated to be shearing of the valves off the ends of the two tanks online. As discussed later under scenario CHEM–01, such a failure mode results in cooling the cylinder to a temperature less than the boiling point of chlorine, terminating the release before all the chlorine is released (actually, about half the total is released). The consequences of this would be no worse than those calculated for a single cylinder rupture, which releases 150 pounds from the building in 18.2 minutes. This results in 53 people being exposed to greater than ERPG–2 and 12 people exposed to greater than ERPG–3 concentrations under conservative daytime dispersion conditions.
- *TA–3–66, 7.6 liters of hydrogen cyanide released.* Hydrogen cyanide (HCN) would form in the basement of the Sigma Building. However, HCN is lighter than air and would be expected to evolve from solution in the basement and reach ground level, at which point it can be modeled as a ground level release. In order to place bounds on the consequences, several

scenarios were run. The most conservative release calculations assumed an instantaneous release of all 7.6 liters of HCN under adverse dispersion conditions, which is extremely conservative. The resulting maximum ERPG–2 and ERPG–3 distances were 0.60 and 0.43 miles (1 and 0.7 kilometers), respectively.

Another calculation was performed similar to those performed for EPA Risk Management Program (RMP) purposes, assuming a constant release rate with all the material released within 10 minutes under adverse dispersion conditions. The resulting maximum ERPG–2 and ERPG–3 distances were 0.45 and 0.28 miles (0.72 and 0.45 kilometers), respectively. A similar case, which assumed evaporation from a puddle under adverse dispersion conditions, produced maximum ERPG–2 and ERPG–3 distances of 0.27 and 0.17 miles (0.43 and 0.27 kilometers), respectively.

EPA RMP-type calculations under conservative daytime dispersion conditions produced maximum ERPG–2 and ERPG–3 distances of 119 yards (109 meters) and 75 yards (69 meters). Because ALOHA-calculated distances of the order of 100 yards or less are overestimates, this release scenario is of marginal consequence under conservative daytime dispersion. Even under adverse dispersion conditions, the ERPG–2 and ERPG–3 distances still did not extend to the Los Alamos townsite; any consequences would be limited to the LANL workforce population. The estimated numbers of people affected by concentrations greater than ERPG–2 and ERPG–3 are 15 and 15, respectively, for conservative daytime dispersion conditions and 44 and 29, respectively, for adverse dispersion conditions. Given collapse of the floor at Sigma, personnel in that facility would likely be severely injured or killed by the seismic event alone. Any survivors would have to rapidly evacuate the structure to avoid exposure to high concentrations of HCN.

- *TA–3–476, 150 pounds of chlorine released.* The consequences of this release are essentially identical to the consequences for accident scenario CHEM–03, as presented in Table G.5.6–1.
- *TA–9–21, 3 pounds of phosgene released.* TA–9–21 is a relatively isolated site at LANL (compared with, for example, TA–3 or TA–55) with a low workforce population in the immediate area. Nonetheless, phosgene is a very toxic gas (the ERPG–3 concentration for phosgene is 1 part per million; whereas, the ERPG–3 concentration or chlorine is 20 parts per million). Using EPA RMP-type release parameters of a constant 10-minute release under adverse dispersion conditions, the ERPG–2 and ERPG–3 distances are 0.76 and 0.0.32 miles (1.2 and 0.52 kilometers), respectively. Under conservative daytime dispersion conditions, the ERPG–2 and ERPG–3 distances decrease to 0.23 and 0.10 miles (0.37 and 0.16 kilometers), respectively. The estimated number of people affected by concentrations greater than ERPG–2 and ERPG–3 is 2 and 1, respectively, under either adverse or conservative daytime dispersion conditions.
- *TA–43–1, 30 liters of formaldehyde released.* This release was modeled because it is the largest inventory of easily dispersed (by air) carcinogens at LANL. The Los Alamos Medical Center is adjacent to the Health Research Laboratory, just across the bridge from LANL in the town area.

Similar to EPA RMP criteria, a 10-minute release was modeled under both adverse and conservative daytime dispersions. Under adverse dispersion, the ERPG–2 and ERPG–3 distances were calculated to be 0.68 and 0.41 miles (1.1 and 0.66 kilometers), respectively. Under conservative daytime conditions, the ERPG–2 and ERPG–3 distances were 0.17 and 0.10 miles (0.27 and 0.16 kilometers), respectively.

The number of people exposed to concentrations greater than ERPG–2 and ERPG–3 under adverse dispersion conditions are 60 and 23, respectively. Under conservative daytime dispersion, the number of people exposed to greater than ERPG–2 and ERPG–3 is 11 and 6, respectively.

The MAR (dominant contributors), earthquake frequencies, and accident conditions are the same for all four SWEIS alternatives; consequently, accident consequences across the alternatives are also projected to be comparable.

G.5.4.2 *SITE–02, Site-Wide Earthquake Causing Damage to Low- and Moderate-Capacity Structures/Internals*

As discussed in section G.5.4, the frequency of SITE–02 is 4.4 x 10^{-4} per year. The source term and consequences of this accident are also addressed in section G.5.4.

Consequences of SITE–02 for Facility Workers and the Public

In this earthquake scenario, the same conservative approach is used as was used in SITE–01. Facilities that sustain structural collapse would essentially consider all material in a facility as MAR. This includes stored material that could sustain damage from higher magnitude earthquakes. As with the SITE–01 scenario, for facilities that sustain internal damage only, the process material is considered to be at risk. Facilities that do not sustain damage do not contribute to MAR. Once the facility is considered to be damaged, the same conservative values (as were applied from SITE–01) for determining the source terms were used.

Moderate-capacity structures/internals subject to damage and resulting in radiological releases for a 4.4 x 10^{-4} annual frequency earthquake include TA–16–205 (Weapons Engineering Tritium Facility internals damage), TA–18–32 (Kiva #2 structural failure), TA–18–116 (Kiva #3 structural failure), TA–18–168 (SHEBA structural failure), TA–50–69 (WCRRF structural failure), and TA–55–4 (Plutonium Facility internals damage). The dominant MAR and source terms for moderate-capacity structures/internals are associated with TA–50–69 and TA–55–4.

For the 4.4 x 10^{-4} annual frequency earthquake, the dominant source term contributors include the identified moderate-capacity structures/ internals (TA–50–69 and TA–55–4) and the low-capacity structures/internals evaluated for Scenario SITE–01. The mean collective population dose is projected to total 41,340 person-rem (TEDE), resulting in approximately 24 excess LCFs. Most of the increase in exposure over the SITE–01 results comes from plutonium releases due to internal failures at the Plutonium Facility (TA–55–4); together, the TA–55–4 contribution and the contribution from the low-capacity facilities identified in SITE–01 account for 95 percent of the total integrated population dose. No acute fatalities are predicted to result from the earthquake event.

A member of the public residing at the Royal Crest Trailer Park has the potential of receiving concurrent exposures to releases from TA–3–29, TA–50–1, TA–50–69, and TA–55–4 for the postulated earthquake event. The MEI dose for this receptor location is conservatively projected to total 34.3 rem (TEDE) and primarily results from postulated releases associated with TA–55–4 (Plutonium Facility) TA–50–37 (RAMROD), and TA–3–29.

The MAR (dominant contributors), earthquake frequencies, and accident conditions are the same for all four SWEIS alternatives; consequently, accident consequences across the alternatives are also projected to be comparable.

Chemical release consequences also have been calculated. Chemical releases for SITE–02 include the same releases as for SITE–01, plus additional releases of 6,100 gallons of nitric acid and 5,200 gallons of hydrochloric acid from tanks at TA–55. These tanks are located within a few hundred feet of one another, and the consequences of the hydrochloric acid release are far greater than the nitric acid release. Accordingly, the hydrochloric acid release was modeled in detail (note that no emergency response actions are assumed, with exposure assessed as though the persons exposed are located outdoors; both assumptions are conservative). The hydrochloric acid tank is contained inside a berm; consequently, the release rate is limited by the surface area within the berm.

Consequence analyses were performed assuming a puddle of hydrochloric acid, which is the condition expected following seismic failure of the tank. The consequences of the release are provided in Table G.5.4.2–1

G.5.4.3 *SITE–03, Site-Wide Earthquake Causing Damage to All Structures/ Internals*

As discussed in section G.5.4, the frequency of SITE–03 is 7.1 x 10^{-5} per year. The source term and consequences of this accident are also addressed above in section G.5.4.

Consequences of SITE–03 for Facility Workers and the Public

In this case, high-capacity facility structures are subject to damage and collapse. Once these facilities are considered to be damaged by the earthquake, conservative values are used to estimate the source terms. These values are consistent with the conservative assumptions used in SITE–01 and SITE–02, but consider the larger magnitude of this earthquakes. The increase in impacts is associated with the greater inventories that are affected by the earthquake.

High-capacity facility structures subject to damage and resulting in radiological releases for a 7.1 x 10^{-5} annual frequency earthquake include TA–16–205 (Weapons Engineering Tritium Facility structural failure), TA–54 Area G (TRU drums overturn), TA–55–4 (Plutonium Facility structural failure), and TA–55–185 (TRU Waste Staging Facility structural failure). The dominant MAR and source terms for this scenario are associated with TA–3–29, TA–54 Area G, and TA–55–4.

For the 7.1 x 10^{-5} annual frequency earthquake, source term contributions include the identified dominant high-capacity structures (TA–54 Area G and TA–55–4), the other dominant moderate-capacity (TA–50–69), and low-capacity (TA–3–29, TA–50–1, TA–50–37, TA–54–38, and TA–54 Area G) structures/ internals. The mean collective population dose is projected to total 210,758 person-rem (TEDE), resulting in approximately 134 excess

TABLE G.5.4.2–1.—*Consequences of a Hydrochloric Acid Release*

POINT OF COMPARISON	ERPG–2	ERPG–3
Distance, Adverse Dispersion	2.0 miles	0.72 miles
Distance, Conservative Daytime Dispersion	1.0 miles	0.44 miles
Adverse Dispersion, Exposed Population	194	93
Conservative Daytime Dispersion, Exposed Population	124	36

LCFs. Projected doses and associated health effects primarily result from the postulated releases associated with TA–55–4 (accounting for almost 82 percent of the total) and TA–3–29 (accounting for an additional 14 percent of the total). No fatalities from acute radiation exposure are predicted to result from the earthquake event. The bounding dose at the MEI location in the Royal Crest Trailer Park is approximately 247 rem. The LANL seismic event exposures are almost exclusively from inhalation of plutonium, for which the exposures are more protracted and the acute effects are correspondingly reduced or absent.

The chemical release consequences for SITE–03 are the same as those for SITE–02 (section G.5.4.2).

The MAR (dominant contributors), earthquake frequencies, and accident conditions are the same for all four SWEIS alternatives; consequently, accident consequences across the alternatives are also projected to be comparable.

Recent and ongoing seismic studies have identified the potential for ground faulting at the CMR Building (TA–3–29). The assessment of ground faulting impacts on facility damage is difficult to quantify. For the CMR Building, the facility structure is assumed to collapse as part of the SITE–01 earthquake, with the CMR basement vault being intact until an earthquake magnitude comparable to a HCLPF of 0.34 *g* (frequency of 7.1 x 10^{-5} per year). The annual frequency associated with significant (greater than 50 centimeters) fault displacement is estimated to be 1 to 3 x 10^{-5} per year. Should fault displacement at the CMR Building occur in addition to other SITE–03 impacts, additional releases from the CMR Building could result. A conservative sensitivity assessment of this impact was completed. It should be reiterated that a detailed understanding of the additional damage and associated releases at the CMR Building has not been completed. The conservative sensitivity assessment results in an additional 133,823 person-rem collective population dose, resulting in about 99 additional excess LCFs. The MEI doses would increase by 133.9 rem at the Los Alamos townsite and 99.3 rem at the Royal Crest Trailer Park.

G.5.4.4 *SITE–04, Site-Wide Wildfire Consuming Combustible Structures and Vegetation*

General Scenario Description

The LANL site and surrounding vicinity are generally forested areas with high fuel loading. Wildfires are frequent occurrences on nearby U.S. Forest Service land, with obvious potential for encroaching on the LANL site, as demonstrated by recent events. For this site-wide accident, it is postulated that a wildfire is initiated to the southwest of LANL near the border of the Bandelier National Monument and the Dome Wilderness Area. While there is a potential for initiation of a wildfire at many locations within and near the LANL site, this location was considered as resulting in the most widespread impact to the site and surrounding area.

The fire begins mid day in the late April through June time frame, at a time of high or extreme fire danger, and is not extinguished in the first hour. The initial location is in an area populated with heavy ponderosa pine fuels that are found between roughly 6,500 and 8,200 feet (1,980 and 2,500 meters) elevation. As the fire grows, local jurisdictions respond to the fire, but are not effective due to remoteness, travel time, lack of road access, fire behavior, etc. Resources from more distant jurisdictions are alerted, but cannot arrive in a short time because of distance, limited roads, and opposing evacuation traffic. It proves impossible to put out the fire with the available resources and existing forest access before it enters the laboratory. Unlike the Water Canyon fire (greater than 3,000 acres [1,200 hectares] in June 1954), La Mesa fire (15,270 acres [6,180 hectares] in June 1977), Dome fire (16,500 acres [6,680 hectares]

April 25 to May 5, 1996), and Oso fire (greater than 5,000 acres [2,000 hectares] in June 1998), the weather does not change in time to prevent the fire from sweeping across the western part of LANL and into the townsite.

This specific analysis assumes a common meteorological situation that favors the fire. In this scenario, the fire begins about 10:00 a.m., reaches a size of 1,000 acres (400 hectares) in 3 hours, and becomes a well developed crown fire on a broad fire front containing 6,000 acres (2,400 hectares) in the second day. Like the La Mesa fire (Foxx 1981), at times it advances at a rate of 38 chains[1] per hour (0.44 miles [0.7 kilometers]). It starts spot fires 0.5 to 1.25 miles (0.8 to 0.2 kilometers) in advance, aided by prevailing southwest winds of 20 miles per hour and low daytime humidity. It easily jumps canyons and existing fuel break lines around LANL and the townsite.

The daytime convection column reaches to 20 or 25,000 feet (6 to 7,600 meters). In the Oso fire, the fire burned as actively at night as in the day, with flame heights on the order of 100 feet (30 meters). In this scenario, in order to have a conservative (low height) plume rise, at night the temperature drops and the relative humidity increases. The nighttime plume rise is then about 2,000 feet (600 meters). The fire regains its intensity at 10:00 a.m. each day. Following fire passage, the smoldering remains of vegetation and structures emit smoke and contaminants at the surface level.

The fire reaches State Road 4 and State Road 501, the southwest edge of LANL, at noon on the second day (see Figure G.5.4.4–1). Protective actions are already underway by LANL, such as relocating some radionuclides and barricading some windows, and releasing nonessential personnel following existing emergency plans. (Note that for this analysis, credit is given only for those protective measures that can be easily undertaken, such as ceasing operations or simple material transfers, are given credit.) The fuel break along these roads proves inadequate. At this point, the fire has progressed in areas where access is limited, hampering fire suppression activities due to concern for the safety of the firefighters. A control line is established at Pajarito Road and resources are concentrated there. Consequently, Pajarito Road is closed and not available for public evacuation. The fire burns forest to the west of and within LANL, but its eastern extent within LANL is constrained by pinyon-juniper woodlands and defined by fuel continuity and density.

From aerial photographs, it is estimated that these continuous fuel lines threaten TA–37, TA–15, TA–16, and TA–66, and those TAs to their west, as well as areas in and on the edge of the forested canyons. Following the continuous fuel lines and steered somewhat by southwesterly winds, the fire enters and crosses Pajarito Canyon and Two Mile Canyon, and by 1:00 a.m. of the third day burns up to the Pajarito Road control line just west of TA–66.

Although it would be expected that the control line will contain most fires, in this conservative accident scenario an adverse meteorological situation exists. At noon on the third day, aided by a modest daytime wind speed pickup and low relative humidity, the fire crosses the Pajarito Road control line between TA–3 and TA–55. It surrounds TA–3 and TA–48, and enters Los Alamos Canyon either directly or by spotting. The fire continues down Los Alamos Canyon on both sides of Omega Road where TA–41 and TA–2 are located. Because Omega Road continues down Los Alamos Canyon as a dirt road below the Omega site, it is unsafe for firefighters to enter Los Alamos Canyon, and the fire progresses essentially unabated.

From Los Alamos Canyon, the fire climbs onto the mesas where TA–53 and TA–21 are located. The fire also spots into Mortandad Canyon. The canyon fires are necessarily allowed to burn eastward, due to their inaccessibility, until they

1. 80 chains = 1 mile (1.6 kilometers).

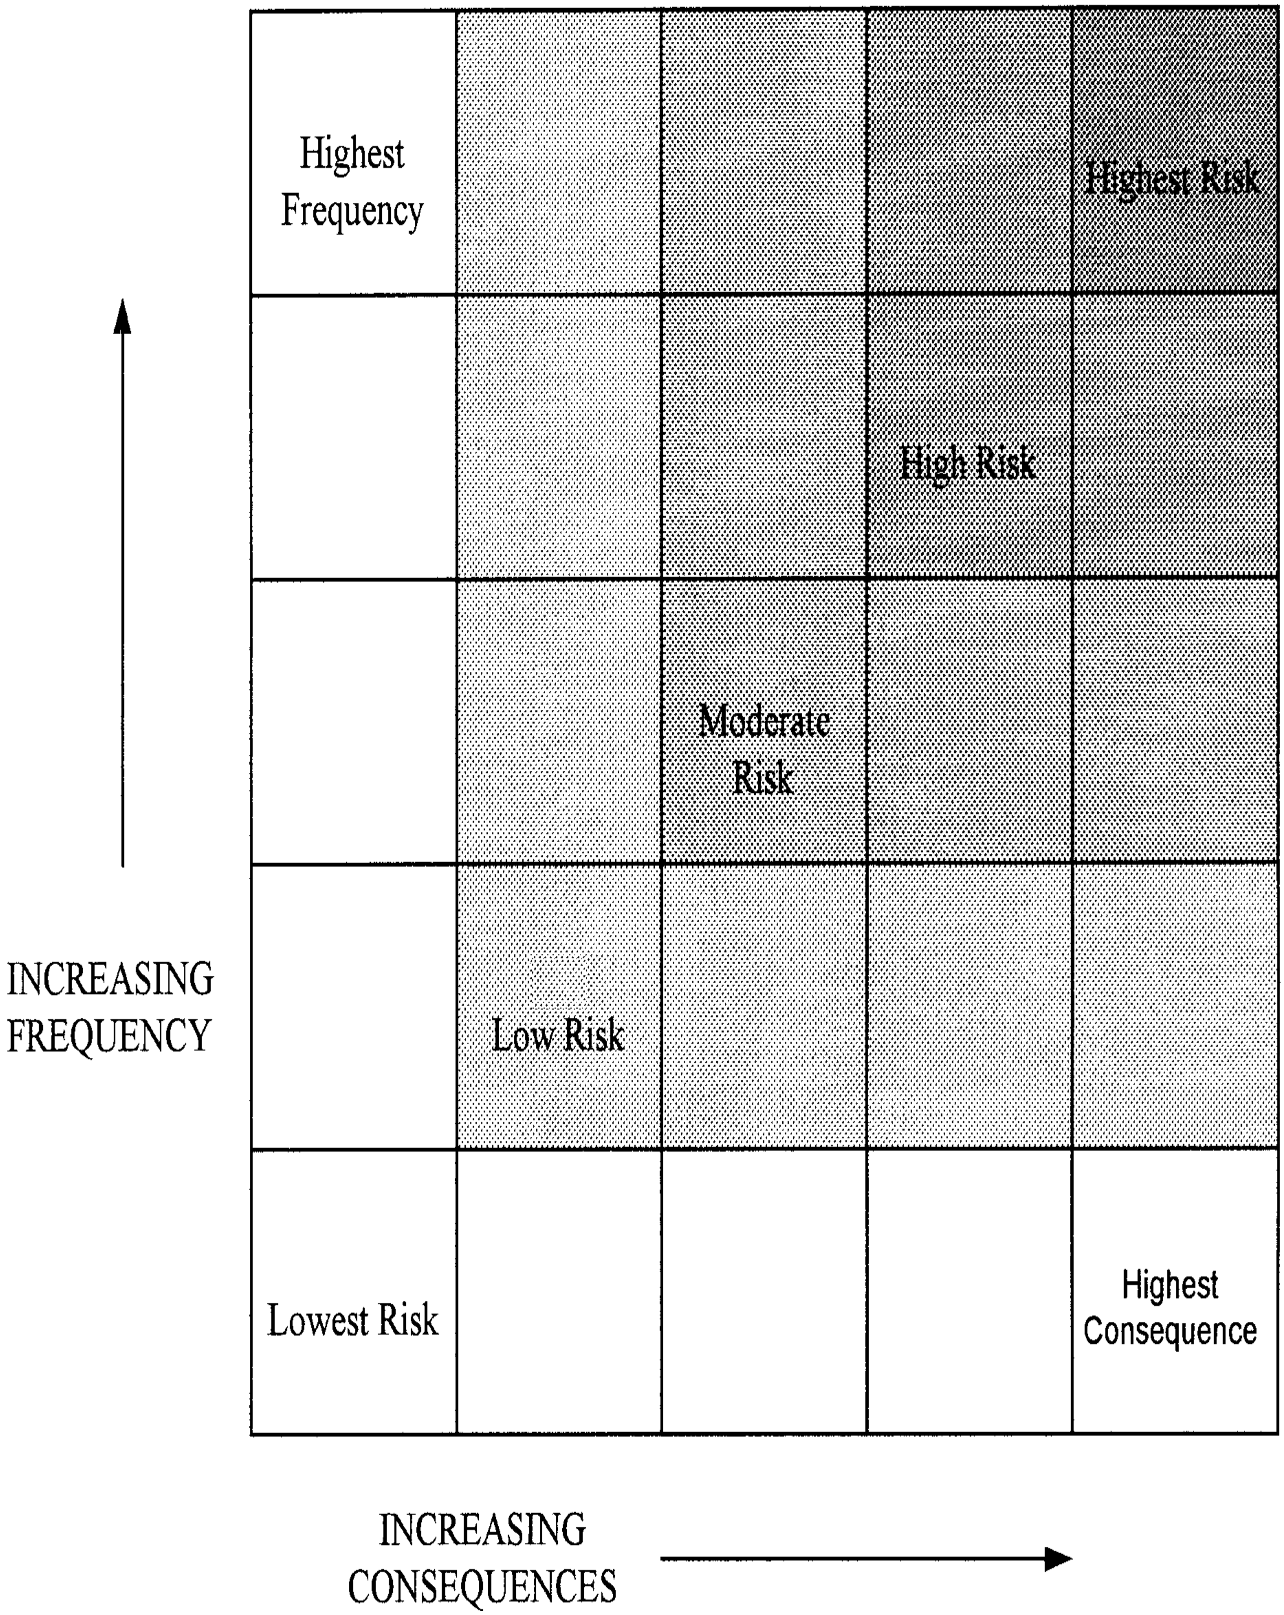

FIGURE G.5.4.4–1—*Location of the Los Alamos National Laboratory*.

reach the thinner stands of pinyon-juniper common to the lower parts of the canyons. There they come under control, by wind and weather changes, lack of fuel continuity, by human interference, or some combination of these. When there are sufficient trees on the canyon walls, fire climbs the walls and then ignites combustible structures and fuel at the canyon edges. It enters the townsite early on the fourth day after initiation.

An alternative fire scenario could have the fire initiate to the west of LANL and townsite in the Santa Fe National Forest of mixed conifer and ponderosa pine. This crown fire, similar to the Oso fire of 1998, travels downslope somewhat more slowly on a broad front. This fire spots only 1/4-mile or more in advance. The present, relatively narrow fuel break around the town and laboratory along State Road 501 would be overreached. This fire also would consume the ponderosa pine and combustible structures in continuous fuel areas over the same western part of LANL and townsite, and the fire would spread down the lengths of canyons until it encountered thin pinyon-juniper stands. It also could not be fought successfully because there is no access to the National Forest west and north of LANL and townsite, and because there is no north-south fuel break comparable to Pajarito Road where a control line can be established and defended. This alternative is not analyzed because the selected scenario is believed to maximize the exposure to the Los Alamos townsite from laboratory releases. The final acreage burned in both scenarios is on the order of 27,000 acres (10,900 hectares) of which about 8,000 acres (3,200 hectares) are within LANL boundaries.

On the LANL site, the fire is assumed to consume all combustible structures in its path that are evaluated as having moderate or higher risk from wildfire under the LANL Building Appraisal Program. The fire also exposes the surface of contaminated earth previously protected by vegetation in the firing sites and canyons. This text separately discusses the exposures from fire burning the soil cover and suspending the underlying soil, and the exposures from burning structures. Exposures from canyon fires are calculated individually, thus enabling the assessment of fires of lesser extent than the site-wide fire.

This accident analysis does not consider off-site damage directly caused by the flames and smoke from LANL fires, and does not address the direct effects of the fire on the townsite. It is recognized that there is continuous fuel joining the National Forest and the residential areas, and that fires in the canyons at LANL also could propagate into the townsite.

Wildfire Frequency

Conditions that Favor Wildfire. These scenarios are quite credible, in view of the present density and structure of fuel surrounding and within LANL and townsite, as well as the occurrence of three major fires in the past 21 years. Some protection is afforded LANL by the fire scars of the previous Dome and La Mesa fires, but there is ample fuel continuity remaining to bring an off-site wildfire to the southwest and western boundary of LANL.

The probability of high to extreme fire danger is determined by the frequency of meteorological conditions of low precipitation for 2 to 3 weeks preceding; low relative humidity for 3 consecutive days; and high temperatures. When the high to extreme fire danger exists in New Mexico in May through July, there are certain to be multiple ignition sources (from lightning, carelessness, and human causes). There is a high frequency of lightning and lightning-caused fires in the Jemez Mountains (Armstrong 1998). From 1975 to 1996, there were 372 fire starts (17.7 per year) in the 40,000 acres (16,000 hectares) of Santa Fe National Forest and Bandelier National Monument adjacent to LANL. Using as input the frequency of different sized fires, the PROBACRE model yielded a 30 percent probability of exceeding

5,000 acres (2,000 hectares) in a 5 year period (Armstrong 1998). Armstrong's calculation was made prior to the 1998 Oso fire, whose inclusion would increase the probability.

The frequency of a large fire encroaching on LANL is estimated as the joint probability of ignition in the adjacent forests, high to extreme fire danger, failure to promptly extinguish the fire, and a 3-day spell of southwesterly to westerly wind over 11 miles per hour (5 meters per second), low humidity, and no precipitation.

Determining the Joint Probability of Occurrence of Weather and Fire Danger Conditions. The probability of occurrence of the weather and fire conditions needed for this scenario were determined using wind data and fire danger data for April through June of 1980 through 1998. These months were chosen on the general knowledge that fire risk and frequency is greater in those months. Note that site-wide fires also are possible, but less probable, in other months besides April through June; thus, the annual frequency of fire-favorable weather is somewhat greater than quantified for April through June.

The fire danger was determined using Energy Release Component (ERC) data obtained from Bandelier National Monument (PC 1998b). The ERC is a component of the National Fire Danger Rating System, and the adjective ratings, such as "moderate" or "extreme," are determined from categories of the ERC, with higher values of the ERC representing conditions of higher fire danger. Above a threshold value of the ERC, the fire danger is "very high" and "extreme," and this threshold value was used to determine days of very high and extreme fire danger. Interpolation was performed to estimate for days when ERC data was missing.

In general, wind direction at any location varies and does not persist in a single direction for a few days. LANL is no exception. At LANL, persistent daytime winds are interrupted for a few hours when nighttime drainage winds occur. However, granting short interludes of drainage flow, there are many instances in which a dominant direction, such as southwesterly, westerly, northerly, etc., can exist for 3 days without precipitation.

For determining fire-favorable weather frequency, 15-minute average wind data from the 11.5-meter level of the TA–59 and TA–6 meteorological towers were used. For each day in April through June of 1980 through 1998, an average afternoon wind was calculated from the 15-minute data in order to eliminate local diurnal changes in wind speed and direction that are common to the area. Average afternoon wind speeds of greater than 10 miles (16 kilometers) per hour were chosen to represent strong winds. While this threshold may seem low for a strong wind, wind gusts of over 30 miles (48 kilometers) per hour and sometimes over 40 miles (64 kilometers) per hour were seen on most days when the afternoon average wind was above 10 miles (16 kilometers) per hour. The wind direction thresholds were set at 180° (southerly, meaning from the south) through 292.5° (west-northwesterly). Three-day periods from the same data set were then examined to determine if the ERC, wind speed, and wind direction fell above (or within) set thresholds. All 3-day periods falling within the set limits were then extracted.

The results show that it is not uncommon to see a 3-day period exhibiting the selected characteristics in a given year, and that when such a 3-day period appears, it is likely that more than one such period will occur within that year. Specifically, the resulting statistics show that of the 19 years examined, 5 of them displayed at least one 3-day period within the limits, or 1 every 4 years. Of these 5 years, 4 of them had an average of 3.6, 3-day periods. (An instance of 5 days in a row is counted as 3, 3-day periods.) This comes to 15.4 instances in 19 springs.

In summary, fire-favorable weather conditions occur on the order of once per year; the ignition sources are prevalent; and fire fighting is hampered by limited accessibility. Therefore, this analysis concludes that a major fire moving up to the edge of LANL is not only credible but likely, probably on the order of 0.1 per year. This frequency is the same for all alternatives.

Dispersion Meteorology

As noted, only certain meteorological conditions are compatible with such a fire. The meteorology of June 7 to 10, 1998, was selected for modeling the accident sequence because these dates were recognized as a recent time of serious fire danger to LANL. These conditions are regarded as conservative, in that in this period the wind is generally from LANL toward the nearby Los Alamos townsite and would result in higher total population doses. Santa Fe is much more distant, and concentrations would therefore be lower. Under northwesterly winds, exposures in Santa Fe (had the alternate scenario been used) would surely be less than exposures to the Los Alamos townsite from the southwesterly winds in this scenario.

Exposures at 100 meters distance from burning exposed soils are calculated using C stability and 6.6 feet (2 meters) per second wind speed. These exposures can be regarded as MEI exposures, although it is unlikely that anyone other than firefighters will be present at that distance. Exposures at 3,300 feet (1,000 meters) are also reported. In canyons, where elongated area sources exist, the calculation provides integrated exposure at 330 and 3,300 feet (100 and 1,000 meters) downwind of the long axis of the area, thus maximizing the exposure. This situation could occur with winds turning to follow the canyon profile, such as under drainage wind conditions. Thus, the calculation applies to plumes that are destined for any receptor within and beyond the contaminated sections of the canyons.

Soil Resuspension Following the Fire

Suspension by the wind of a fraction of the surface soil can occur following denuding of the vegetation. This has the potential of exposing workers returning to the area, as well as the transient public, until the situation has stabilized and vegetation has begun to recover. As proven by the continuing existence of soil and ash following a fire, the suspension of fire residue and of burned soil is very small compared to the bulk quantity that continues to remain. Only the loose material would be suspended, and, if the material is not mechanically disturbed, the rate of suspension would taper off. Even if precipitation halting the suspension did not occur, the wind direction would change many times so that the resuspended material would not be transported as effectively as that from the shorter term, initial release. Consequently, resuspension doses are only calculated for an individual standing directly on the contaminated area.

Large, brief suspensions for unweathered materials occur under mechanical disturbance, such as the passage of vehicles. This is highly dependent upon vehicle speed and wind speed (Figure 4-23, DOE 1994d). The highest, bounding resuspension rate is 1×10^{-2} per passage for a car driven directly through powder tracer material on an asphalt road (DOE 1994d). However, there are no asphalt roads and no fast vehicle traffic on the firing ranges, and most of the contamination is not near roads. Hence, suspension by vehicles will not be of this magnitude and is not included in this analysis. Rather, the direct suspension by the wind is analyzed.

A rate of resuspension is often expressed as the ratio of the airborne concentration and the areal surface contamination, usually with the units of meters^{-1}. This ratio is called the resuspension factor. Its magnitude depends upon the wind speed, particle size, and nature of the cover. The resuspension factor decreases with time due to weathering and downward migration of a portion of the contamination. Although most material remains in the surface soil, it becomes unavailable to the wind. Sehmel (1984) provides a substantive discussion of resuspension factors, their use, and limitations. Note, this concept strictly applies to the resuspension of material deposited from the atmosphere and applied to the soil as tracers in experiments and may not apply to material otherwise incorporated in the soil matrix. Most resuspension factors range from 10^{-5} to 10^{-11} per meter.

Note that the resuspension factor is not the fraction of the material that becomes airborne, and therefore cannot be treated as an airborne release fraction (ARF) or source term for dispersion models. Because of the way the resuspension factor is defined and measured, the concentrations apply only in the immediate vicinity (i.e., above) the contaminated soil. Concentrations beyond the area will be much lower, due to variations in the wind direction and atmospheric diffusion.

Although resuspension factors are highly irregular and poorly defined (Sehmel 1984), they were applied to evaluate residual concerns with reoccupying burned out contamination areas. A conservative resuspension factor of 1×10^{-5} meters^{-1} (sandy soil with charred debris) is selected for use in this analysis (from Section 4.4, Table 4-16, page 4-91, DOE 1994d). The fraction of the suspended contaminant that is respirable (less than 10 micrometers equivalent aerodynamic diameter) at the soil surface following the fire passage, is unknown. The particle size is likely to be large, as the contaminants will be attached to soil particles; but, because it is unknown, an RF of 1.0 is assumed. The appropriate time period for application of this conservative value is probably only a few days long, depending upon precipitation, because resuspension factors decrease by several orders of magnitude with time.

The resuspension factor of 1×10^{-5} meters^{-1} was applied to the mean areal soil concentration in the top layer of the contaminated sites, with the resultant radiological exposures shown in Table G.5.4.4.–1. These are the estimated exposures that could occur if all the contamination in the top soil layer were right at the surface, if there were no precipitation or soil cover, if there were wind, and if the receptor were standing above a spot that represented the average soil contamination for the contaminated portion of the site or canyon. These estimates are limited by the theoretical and experimental problems with resuspension factors.

In practice, before these known contamination areas would be reoccupied following a fire, the potential for exposure would be assessed and protective actions taken as appropriate to minimize exposure to the personnel.

Exposures from Burning Vegetation and Suspended Soil

Open Burn/Open Detonation Dispersion Model. During the burning of a vegetative cover, some fraction of the soil is entrained into the fire and transported and dispersed downwind. Such downwind concentrations of soil contaminants suspended by fire were calculated using the Open Burn/Open Detonation Dispersion (OBODM) model. The Open Burn/Open Detonation Dispersion Model (OBODM) is intended for use in evaluating the potential air quality impacts of the open-air burning and detonation of obsolete munitions and solid propellants at U.S. Department of Defense and DOE installations (DPG 1997). It can be used to calculate peak concentration, time-mean concentration, time-integrated concentration, and particulate deposition from multiple sources. It can consider instantaneous or quasi-continuous releases from point, volume, and/or line sources.

The model predicts buoyant rise of the plume from the burn and uses default mixing depths generally representative of noncoastal regions

TABLE G.5.4.4–1.—*Estimated Inhalation Doses from Resuspension Following Wildfire*

SITE	AREA (m^2)	TOTAL SOIL CONTAMINATION	MEAN SOIL SURFACE CONCENTRATION	AIR CONCENTRATION	INTAKE PER DAY[a]	EFFECTIVE DCF[b] (mrem/μCi)	RECEPTOR DOSE (mrem/day)

Notes:
[a] The breathing rate used is 30.24 m^3/day.
[b] The effective dose conversion factors are for the mixture of nuclides at each firing site and canyon.
[c] These intakes of uranium would exceed the OSHA PEL of 0.25 mg per 8 hours.

in the western United States. The minimum meteorological input consists of wind speed and direction at 10 miles elevation, air temperature, and the Pasquill stability category or the Net Radiation Index. For OBODM wildfire calculations, a conservative stability and wind speed (category C and 2 meters per second at 10 miles height) were selected to maximize the downwind exposures. A stable atmosphere would not represent the mixing conditions in the daytime meteorological situations favorable to a wildfire, and could not exist in the presence of the wildfire.

Vegetation Fire Plume Rise. The OBODM model calculates the plume rise given a fuel loading, rate of burn, and heat content of the fuel. It calculates the resulting concentration distribution at specified receptor points. The fuel model classes and associated rates of burn (defined pursuant to Anderson 1982) were determined by field survey (PC 1998c) and are given in Table G.5.4.4–2.

Caloric values of various terrestrial food plants and seeds are 4.5 to 5.2 cal/gm (Odum 1971). The heat content of dead cellulosic materials does not vary greatly (Simard et al. 1989). For this analysis, the heat content of both grass and of wood were assumed to be 4.95 cal/gm (20.7 J/gm) (Wilgen et al. 1990). The fuel models contain the sum the dead and live vegetation in various conditions of dryness and have an associated rate of fire spread. The range of uncertainty in the fuel load is large enough that the uncertainty in the moisture content, heat content, and rate of burn is not material. The total heat produced is used only to calculate the plume rise, which has only a modest effect on concentrations at moderate to large distances from the source.

Areas of Contaminated Soil Analyzed. The areas of contaminated soil were identified as PHERMEX Firing Site and EF Firing Site in TA–15, Potrillo Canyon (from runoff at the EF Firing Site), DP Canyon and Los Alamos Canyon below TA–21, and Mortandad Canyon below and east of TA–35. The radioactive waste lagoon at the end of TA–35 has cattails in it, but contains water. Acid Canyon received untreated waste water until 1953, then treated waste water until 1963. It has been cleaned up, but residual contamination still shows up in the Acid Weir sediment trap. The area of contamination in Acid Canyon is estimated as 3.3 feet wide by 330 feet long (1 meter wide by 100 meters long) (PC 1998d). Acid Canyon empties into Pueblo Canyon, which also is of low concentrations. Other, numerous contaminated areas that have been covered with clean soil are not at risk of suspension during and following wildfire and therefore were not evaluated. Ten Site Canyon below the Radioactive Liquid Waste Treatment Facility in TA–50 was not evaluated, as its contamination is primarily strontium-90, which has a lower dose conversion factor than plutonium and because it has such low concentrations that it is no longer sampled (PC 1998e).

The contamination levels were obtained from several publications, as identified at various places in this text and in the summary Table G.5.4.4–2. To be conservative, the total amount in the upper tier of sampled soil, usually 0 to 1 or 0 to 3 inches (2.5 or 7.6 centimeters) depth, were assumed to be entirely on the surface and exposed to the fire.

Airborne Release Fractions During Vegetation Fires. The model OBODM requires as input the fraction of contamination present in the fuels being burned. For these calculations, the ratio of this suspended contamination to the mass of fuel burned over the same area was presented to the model. To get this ratio, the mass of contamination suspended during the fire passage is the product of the contamination in the top layer of surface soil and the release fraction. For this assessment, all the contamination in the top layer of soil is assumed to be released with the release and respirable fraction (ARF x RF) appropriate to uranium metal under thermal stress.

For contamination in the soil, duff and litter, the burning temperature is going to be low and the burning time short, with the fire front progressing at 0.2 to 0.44 meter per second in timber and grass, respectively. The possibility of shrapnel in trees is recognized. However, there are few trees around the firing sites, and the release fraction from burning DU is small. Uranium is not capable of continued burning after the fire has departed, and so the burning release time would be short. The ARF x RF for uranium metal under thermal stress is taken from DOE 1994d, Section 4.2.1.2.1, page 4-42. The observed geometric mean ARF x RF is 1 x 10^{-4}, with a 95 percent confidence level ARF x RF of 4 x 10^{-4}. In this analysis, the value 4 x 10^{-4} also is used for beryllium and its compounds in the absence of experimental data dealing directly with beryllium. There are no release fractions available for radionuclides other than plutonium and uranium in the DOE-HDBK-3010-94 (DOE 1994d) or in the Nuclear Fuel Cycle Facility Accident Analysis Handbook NUREG/CR-6410 (NRC 1998). The bounding ARF x RF for powders subjected to thermal stress are 6 x 10^{-5} for nonreactive compounds and 1 x 10^{-5} for reactive compounds (DOE 1994d, Section 4.4.1, page 4-61). For consistency, the conservative ARF x RF of 4 x 10^{-4} also was used for other nuclides in contaminated soils.

Contamination in Plants and Animals. Small mammals have tissue/soil uranium ratios of 10^{-3} and 10^{-4} (Miera et al. 1980), and tissue/soil cesium and strontium ratios on the order of 1.0 (Whicker and Schultz 1982, Table 17). (It is unclear whether these ratios are wet or dry weights in the animals, plants, and soils.) For the reasons of their low concentration ratios, their escape ability, and their very small total mass compared to that of the vegetation, animals are ignored as a source of airborne nuclides in this analysis.

The NRC has published a list of plant/soil concentration ratios (NRC 1977). The ratios for stable strontium and cesium are 0.017 and 0.01, respectively, although there will be cases where observed values differ substantially (Whicker and Schultz 1982). Whicker and Schultz stated that the ratios for uranium range from 10^{-4} to over 10^{-1}, that ratios for plutonium are particularly dependent on chemical form, and that ratios for americium are perhaps 100-fold higher than plutonium. Plants growing where uranium concentrations in surface soils were 20 times to 3,500 times background, have exhibited uranium concentration factors of 0.05 (spring) to 0.08 (fall). Late fall standing dead vegetation at the EF site averaged 320 micrograms uranium per gram of dry vegetation (Miera et al. 1980). Applying this observation, the 1,987 kilograms of vegetation at the EF site would contain 0.64 kilogram of depleted uranium, all of which would presumably become airborne in the fire. Application of the ARF of 4 x 10^{-4} to the EF site soil would produce 0.27 kilogram of airborne depleted uranium. Thus, the dose from burning vegetation could contribute 2.37 times the dose from the suspended soil, and the doses could be 3.37 times the value given for soil alone in the final column of Table G.5.4.4–2.

Wenzel et al. (1987) studied radionuclide concentrations in soil, litter, and vegetation growing in a TRU waste area, and concluded that a higher resolution sampling is needed for cesium-137 and plutonium-239/plutonium-240 to interpret surveillance results and produce reliable risk assessments. Their observations, suggest that the concentrations of these nuclides, and of depleted uranium, in vegetation is always less than the concentrations in the top 0.8 inch (2 centimeters) of soil, and generally an order of magnitude less.

Thus, it is concluded that the doses in the final column of Table G.5.4.4–2 could be increased by a factor of three or four to account for the contamination in the vegetation above ground that becomes airborne.

Beryllium Exposures. The 8-hour time weighted average for worker exposure to

TABLE G.5.4.4–2.—*Summary Table for Contaminated Soil Areas*

SITE	PHYSICAL DIMENSIONS	MEAN SOIL CONTAMINATION	FUEL TYPE FUEL MODEL	BURN RATE	FUEL LOADING	RECEPTOR DOSE AT 100 m AND 1,000 m
EF Site[a]	200 ft/61 m radius 11,690 m^2	542 ppm area-weighted uranium[b]; 675 kg total	Grass Fuel Model 1	78 chain/hr (0.44 m/s)	1,987 kg; 0.74 ton/ acre (0.17 kg/m^2)	0.21 mrem (0.01 mrem)
PHERMEX Site[a]	200 ft/61 m radius 11,690 m^2	456 ppm area-weighted[b]; 568 kg total	Grass Fuel Model 1	78 chain/hr (0.44 m/s)	1,987 kg; 0.74 ton/ acre (0.17 kg/m^2)	0.18 mrem (0.008 mrem)
PHERMEX Site[c]	200 ft/61 m radius 11,690 m^2	Simple average 31.7 ppm Beryllium in 0 to 3 inch soil depth[d]	Grass Fuel Model 1	78 chain/hr (0.44 m/s)	1,987 kg; 0.74 ton/ acre (0.17 kg/m^2)	0.8 $\mu g/m^3$ (0.0005 $\mu g/m^3$)[i]
Potrillo Canyon[e]	4 m x 300 m 1200 m^2	58 kg uranium 0 to 15 cm depth	PIPO-Canyon Fuel Model 2	35 chain/hr (0.20 m/s)	566 kg; 2.1 ton/ acre (0.47 kg/m^2)	0.0016 mrem (3.5 x 10^{-4} mrem)
Mortandad Canyon[g]	4 m x 3,400 m 13,600 m^2	Surface inventory of 4.7 x 10^9 pCi of mixed nuclides	PIPO-Canyon Fuel Model 2	35 chain/hr (0.20 m/s)	6,415 kg; 2.1 ton/ acre 0.47 kg/m^2	4.7 x 10^{-4} mrem (3.6 x 10^{-5} mrem)
DP Canyon[f,g]	3 m x 1,200 m 3,600 m^2	1.6 x 10^7 pCi TRU surface inventory	PIPO-Canyon Fuel Model 2	35 chain/hr (0.20 m/s)	1,700 kg; 2.1 ton/ acre (0.47 kg/m^2)	2.8 x 10^{-4} mrem (1.6 x 10^{-4} mrem)
Los Alamos Canyon[g]	3 m x 6.3 km 18,900 m^2	1.2 x 10^7 pCi of TRU surface inventory	PIPO-Canyon Fuel Model 2	35 chain/hr (0.20 m/s)	8,920 kg; 2.1 ton/ acre (0.47 kg/m^2)	1.5 x 10^{-7} mrem (1.4 x 10^{-7} mrem)
Acid Canyon[g,h]	1 m x 100 m 100 m^2	16.4 x 10^6 pCi of TRU surface inventory	PIPO-Canyon Fuel Model 2	35 chain/hr (0.20 m/s)	47.2 kg; 2.1 ton/ acre (0.47 kg/m^2)	4.1 x 10^{-5} mrem (3.0 x 10^{-6} mrem)
Pueblo Canyon[g]	3 m x 9.5 km 28,500 m^2	2.5 x 10^8 pCi of TRU surface inventory	PIPO-Canyon Fuel Model 2	35 chain/hr (0.20 m/s)	13,450 kg; 2.1 ton/ acre (0.47 kg/m^2)	2.2 x 10^{-8} mrem (2.0 x 10^{-8} mrem)

[a] Data from DOE 1995a Appendix D.
[b] 456 ppm and 542 ppm area-weighted average depleted uranium in 0 to 3 inch depth of surface soil of density 1.4 g/cm^3 yield 568 kg and 675 kg depleted uranium.
[c] Data from Fresquez 1994, results of the soil sampling survey conducted over active RCRA firing site TA–15–184 (PHERMEX).
[d] Simple average concentration in surface soil of density 1.4 g/cm^3.
[e] Data from Miera et al. 1980.
[f] Width and length from PC 1998f.
[g] Data from Environmental Surveillance Reports (ESR) for 1992 (LANL 1994e), 1995 (LANL 1996r), and 1996 (LANL 1997c).
[h] Data from Acid Weir site, Table 5-14 of ESR 1996.
[i] For beryllium, rather than the TEDE or integrated concentration, the peak concentration is provided for comparison to standards. The acceptable maximum peak for a maximum of 30 minutes is 25 $\mu g/m^3$ (NIOSH 1997).
[j] Due to the very long line source oriented down the canyon and the wind blowing down the canyon, dose does not change much with distance down the canyon. In fact, at 10,000 m in Los Alamos Canyon, the dose is effectively the same as at 1,000 m.

beryllium and its compounds is 0.002 milligram per cubic meter. The acceptable maximum peak for a maximum duration of 30 minutes is 0.025 milligram per cubic meter (NIOSH 1997). These are not thresholds that will protect all people but are useful for comparison to the concentrations from burning over the PHERMEX site. The beryllium concentrations calculated by OBODM (Table G.5.4.4–2) were 0.0008 milligram per cubic meter, much less than these thresholds.

Conclusions as to Doses Downwind from Firing Sites and Canyon Fires. The doses at 330 feet and 3,300 feet (100 meters and 1,000 meters) downwind from fires over individual firing sites and canyons are provided in Table G.5.4.4–2. The doses assume that the receptor remains at those locations for the full time of the plume passage. This can be a long time, as the fire front advances at about 0.7 foot per second (0.2 meter per second) in the canyon timber. At this speed, the fire takes 13.5 hours to burn the contaminated area of Pueblo Canyon, 8.9 hours for Los Alamos Canyon, 4.8 hours for Mortandad Canyon, and 1.7 hours for DP Canyon, but only 0.42 hours for Potrillo Canyon and 20 minutes for the EF site.

The largest doses from the vegetation fires are at 330 feet (100 meters) downwind of the firing sites, EF (0.21 millirem), and PHERMEX (0.18 millirem). The 5×10^{-7} LCF per millirem risk factor can be applied to the doses in Table G.5.4.4–2, to receive assurance that there are no effects expected from the radiological exposures from burning vegetation and ground cover over soils. If the total area of contamination is small, such as for the firing sites and Acid Canyon, then the same values would apply for any wind direction. For the other canyons, however, the exposure is integrated for the entire length of the canyon fire, and so the exposure to the side of the canyon would be less than given in Table G.5.4.4–2.

Because the canyons are parallel, a receptor cannot be directly downwind from more than one canyon, and hence, the exposures from multiple canyons should not be added to obtain a new MEI dose. In order for a receptor to receive exposure from multiple canyons, the wind would have to be transverse to them, as it would be in this site-wide fire with the southwesterly winds. However, if the wind were transverse to multiple canyon fires, the orientation of the canyons would assure that the dose from each would be much less than those shown at 100 meters distance in Table G.5.4.4–2. One must conclude that, no matter the orientation of the wind, sources, and receptors, the MEI dose from site-wide vegetation fires must be less than 1 millirem.

Delayed Emissions Following Building Fire

The smoke or emissions from building remains following the fire passage were not modeled. The entrainment of surrounding air by strong fires will capture much of the delayed emissions that occur soon after passage of the fire front, converting them into an elevated release as part of the main fire. However, in the LANL landscape there may not be an intense, continuous fire front; hence, some of the contaminants in the surface emissions may travel and disperse at low elevations. The relative amount of the contaminant that is and is not entrained into the main fire plume cannot be evaluated.

Evaluation of Building Fires

This section analyzes potential individual and population radiological and chemical exposures from buildings burning as a result of wildfire initiation. Each building was first screened for its vulnerability to wildfire. Those that were evaluated as vulnerable were then screened for chemical and radiological inventories. For those with significant inventories, the doses from the fires were then obtained from previous fire analyses (such as in SARs or this SWEIS) or newly calculated using the MACCS code.

Criteria and Process for Determining Building Vulnerability to Wildfire. The evaluation of vulnerability to wildfire is on the basis of building construction, materials and exposure, slope, and the quantity and structure of external fuel as described below. The total wildland fire vulnerability was calculated for this SWEIS by the LANL Fire Protection Group. The vulnerability is the product of the structure hazard times the sum of the fuel hazard and slope hazard, as defined below.

The Structure Hazard Rating considers the combustibility of the exterior structure:

- Underground—0
- Noncombustible exterior (windowless)—1
- Noncombustible (window exposures)—2
- Combustible exterior—3

Fuel Hazard. This is the product of two components, fuel loading and distance factor. The fuel loading is taken as zero for short grass and asphalt, and for other conditions is determined by the fuel model type, as described in *Aids to Determining Fuel Models For Estimating Fire Behavior* (NWCGP 1982).

The distance factor, DF, expresses the distance of the fuel from the structure.

- DF—0, distance is greater than 4 times the height of the fuel.
- DF—1, distance is greater than 2 times the height of the fuel.
- DF—2, distance is the height of the fuel.
- DF—3, distance is less than 1/2 the height of the fuel.

Slope Hazard. Exposing slopes are rated as follows:

Slope Hazard	Slope
5	Mild (0 to 5%)
10	Moderate (6 to 20%)
15	Steep (21 to 40%)
20	Extreme (41% and greater)

The total vulnerability is then calculated as the product of the structure hazard times the sum of the fuel hazard and slope hazard. This number is converted to a word description as follows:

Numerical rating	Vulnerability
0 to 5	None
6 to 49	Very Low
50 to 79	Low
80 to 149	Moderate
150 to 259	High
260 and above	Extreme

Note that this LANL system does not provide a probability that a wildfire will approach the building, or that any particular building **will** burn in a fire. Rather, it sorts which buildings are more likely to be damaged or destroyed should a wildfire approach. Table G.5.4.4–3 lists the buildings that have a moderate or higher risk, have also been assigned a hazard category in the publication LANL 1998a, and were subsequently evaluated for public exposure from wildfire. Other buildings have no significant amounts of MAR and were not evaluated for this accident analysis.

For each building that has a moderate or higher vulnerability and appears in LANL 1998a, a determination was next made as to whether further analysis of public exposure was needed. Table G.5.4.4–4 provides the results. Some buildings were eliminated based on updated inventories, as having no significant inventories, or an inventory that was present only for brief periods. These determinations appear in the columns headed "Comments and EIS Assessment." The comments column

TABLE G.5.4.4–4—*Final Vulnerability and Consequence Assessment of Building Wildfires*

TECHNICAL AREA	BLDG. NO.	FACILITY NAME	COMMENTS	SWEIS ASSESSMENT
TA–02	4	Laboratory Storage Building, OWR	Former Facility Manager stated that no residual contamination exists in this building, and it would not add contaminants to the plume during a wildfire.	Eliminated based on no residual contamination or inventories.
TA–02	44	Laboratory Storage Building OWR	Former Facility Manager stated that two resin exchange columns exist in this building, and samples could be collected and analyzed to determine the amount of contamination that currently remains in the ion exchange columns. He indicated that the remaining contamination would be very small and may contain cobalt-60.	No data available and therefore could not be analyzed. Public exposures from the small inventory would be bounded by other building fires. Facility is scheduled for disposal.
TA–02	1	Omega West Reactor (OWR)	Former Facility Manager stated that reactor systems were flushed and analyzed as part of the decontamination and decommissioning process, the cooling systems are dry, the reactor vessel or housing is still radioactive, but is encased in a stainless steel vessel that should not burn.	Fuel has been removed; Reactor is in the process of completing any decontamination and decommissioning activities; eliminated based on no wildfire risk to inventory
TA–03	66/451	Sigma Building	130 kg of fines in oil, plus 100 electrodes each 1/4 inch thick by 8 inch by 4 ft. long. Remainder of 65,000 kg of DU is in fixed storage cabinets of 1/2 hour fire resistance. All material is in the basement. Information from facility walkdown conducted by GRAM, Inc. (Garvey 1998) nitric acid, fuming (6,484 lbs.), hydrochloric acid (3,130 lbs.), hydrofluoric acid 48 to 51% (490 lbs.).	The maximum dose from the inventory of 65,000 kg calculated for this scenario was 3.0×10^{-5} rem 50 yr. committed effective dose equivalent (EDE) at approximately 10 km from the release point (Young 1998). Chemicals below grade level and not likely to be affected by fire.
TA–08	24	Isotope Building	The facility is used only intermittently for storage of radioactive material; operations, in the event of a wildfire, would not be conducted or would be terminated and material would not be stored in this facility.	Eliminated based on the intermittent use of the facilities
TA–08	70	Nondestructive Test		Eliminated based on the intermittent use of the facilities

TABLE G.5.4.4–4—*Final Vulnerability and Consequence Assessment of Building Wildfires*-Continued

TECHNICAL AREA	BLDG. NO.	FACILITY NAME	COMMENTS	SWEIS ASSESSMENT
TA–15	203/213	PHERMEX Cavity Shelter	There is no known residual contamination or inventory of radioactive material in this building.	Eliminated based on no residual contamination or inventories
TA–15	313	Radiographic Support	Radiation is only present when machine is operating. Concrete blocks surround equipment; therefore, the equipment would not be at risk in a wildfire.	Eliminated based on no residual contamination or inventories of radioactive material
TA–16	205	Weapons Engineering Tritium Facility (WETF)	100 g, tritium in process; vault storage: 60 g in tubs, 1,200 g in Lp-50 Containers. Information from facility walkdown conducted by GRAM Inc. (Garvey 1998) March 2, 1998 FSAR available, No SER.	The maximum dose (MEI) was calculated as 0.25 rem at 4.85-km distance. Doses are less at shorter distances due to the plume rise. The population dose is 189 person-rem within the 80.5-kilometer (50-mile) radius. (Young 1998)
TA–18	32	Critical Assembly Building	All three kivas are concrete construction, and materials are contained in a concrete vault within the kivas.	Eliminated based on no wildfire risk to the inventories
TA–21	155	Tritium Science Test Assembly (TSTA)	200 g tritium. Information from facility walkdown conducted by GRAM Inc. (Garvey 1998).	The RAD–05 aircraft crash and fire accident consequences from a 200 g release of tritium oxide were 24 person-rem population exposure and mean MEI dose of 0.012 rem at State Road 5 (360 m). These consequences are 25% less under the Reduced Operations Alternative.
TA–21	209	Tritium Science and Fabrication Facility	100 g tritium Information from facility walkdown conducted by GRAM Inc. (Garvey 1998).	Scaling of the RAD–05 aircraft crash and fire accident consequences to a 100 g release of tritium in oxide form results in 12 person-rem population exposure and mean MEI dose of 0.006 rem at Route 502 (360 m).
TA–35	213	Target Fabrication	1 kg beryllium; 10 lbs. boron trichloride; 5 lbs. (solid), 8 kg (solutions) cyanide; 3 lbs. diborane, 3 l. formaldehyde, 4 lbs. metal carbonyls, 171 l nitric acid, 1 lb. phosphene, 20 Ci tritium, 10 kg U-235 Information from facility walkdown conducted by GRAM Inc. (Garvey 1998).	There would be only a very small dose, as 20 Ci is a 1/10 the inventory of the RAD–05 accident, and the TA–35 source is further from the townsite than is the TA–21 source. The chemical inventories are small and therefore not modeled.

TABLE G.5.4.4–4—*Final Vulnerability and Consequence Assessment of Building Wildfires*-Continued

TECHNICAL AREA	BLDG. NO.	FACILITY NAME	COMMENTS	SWEIS ASSESSMENT
TA–41	4	Experimental Science Laboratory Building	Approximately 0.02 g tritium (about 200 Ci) as residual contamination.	The RAD–05 aircraft crash and fire accident consequences from a 200 g release of tritium in oxide form at TA–21 were 24 person-rem population exposure and mean MEI dose of 0.012 rem at Route 502 (360 m).
TA–43	1	Health Research Laboratory	30 liters formaldehyde Information from facility walkdown conducted by GRAM, Inc. (Garvey 1998).	Evaluated in the SWEIS earthquakes. The ERPG–2 and ERPG–3 distances were 0.17 and 0.1 miles (0.27 and 0.16 km), respectively, under conservative daytime dispersion conditions. The number of people exposed to greater than ERPG–2 and ERPG–3 were 11 and 6, respectively.
TA–48	1	Radiochemistry Laboratory	See BIO for TA–48, approved 3/31/97.	Dissolving wing fire (Scenario 2) 0.3 mrem at 720 m, Alpha wing fire is 5.4 mrem at 720 m or at the Royal Crest Trailer Park. The whole facility fire is postulated to be 50 mrem. Chemical exposures at this location are less than ERPG-2.
TA–53	1	Laboratory Accelerator Building		Eliminated based on unavailability of the small inventory to wildfire, per walkdown provided by Chris Del Signore
TA–53	3	Linear Accelerator Building		Eliminated based on unavailability of the small inventory to wildfire, per walkdown provided by Chris Del Signore
TA–54	153, 224, 226, 229, 230, 231, 232, 283, 33, 48, 49, and Pad 2	Waste drum preparation, and domes	Evaluated in RAD–08.	The consequences of the aircraft-initiated fire in RAD–08 were 400 person-rem population exposure, and a mean MEI dose of 22 rem at both White Rock and Pajarito Road.

contains suspected inventories, pending verification.

Public Exposures from Burning Buildings. Those building fires with integrated population and MEI inhalation exposure from burning buildings are also presented in summary Table G.5.4.4–5. Analyses already existed for some buildings in SARs and elsewhere in this SWEIS, such as the case for the aircraft crashes and fires in TA–21 and TA–54, identified as RAD–05 and RAD–08. The exposures assume no sheltering inside buildings or vehicles and that no protective actions are taken by the individual at those locations. Although Area G is not in the direct path of the fire, it borders a canyon and could be victim to a canyon fire even in the absence of a site-wide fire. Therefore, it also has been included in the wildfire analysis. The reader may evaluate the consequences of a partial site-wide wildfire and/or canyon fires by selecting individual canyons from summary Table G.5.4.4–2 and individual facilities from Table G.5.4.4–4 for summation.

Vulnerable buildings and the outdoors in the fire path were screened for their chemical inventories. No new inventories were found that were not available for the analysis of the site-wide earthquake (sections G.5.4.1 and G.5.4.2). For fire-vulnerable facilities, the earthquake chemical results were accepted for the site-wide fire, and entered into Table G.5.4.4–4. Note that, whereas the chemical releases in the earthquake were at ground level, the chemicals in the plume from the fire would be at higher elevations, and the concentrations at ground level would be much less.

Note that the meteorology used for dispersion in the different SARs and for the radiological accidents RAD–05 and RAD–08 in this SWEIS are not the same as that posed for this wildfire. The SARs use more conservative dispersion with low wind speed and stable conditions and will have a higher dose than if they had used wildfire meteorology. The wildfire has significantly stronger wind and a neutral or unstable atmosphere, strongly affected by the fire itself. The SWEIS uses representative meteorology for an entire year and presents a mean MEI (section G.2.4). The representative meteorology includes winds blowing away from any receptor, and the full range of stabilities, weighted by frequency of occurrence. The wildfire meteorology would possibly result in the same dose to the MEI and population as does the mean meteorology because it may be close to the annually typical stability and wind speed. It was concluded that, due to the magnitude of the doses and the conservative assumptions in the wildfire scenario, and the uncertainty of the population distribution during the fire, new calculations were not warranted for RAD–05 and RAD–08.

There are no differences in wildfire frequency among the alternatives. The consequences do not vary with alternatives, except that the inventory and consequences are reduced by 25 percent in RAD–05 under the Reduced Operations Alternative.

Population Exposures

The following information on the exposed population is based upon the Los Alamos County Emergency Plan and the LANL Closure Plan (PC 1998f). In the event of a wildfire approaching from the south, LANL would begin evacuation of the southern area of LANL as soon as it was determined that the fire posed a threat, and proceed north with the evacuation. Personnel deemed essential to shutdown operations would remain until such actions were completed. Some emergency response personnel and security personnel would remain at all times in some areas. There are 10,200 LANL employees (including contractors), of which approximately 4,000 live outside of Los Alamos County and 6,200 within Los Alamos County. The main hill Road 502 will evacuate 800 cars per hour, and the combination of the

TABLE G.5.4.4-5—*Consequence Summary for Building Fires*

TECHNICAL AREA	BUILDING NUMBER	FACILITY NAME	SWEIS ASSESSMENT
TA–03	66/451	Sigma Building	The maximum dose calculated for this scenario was 3 x 10^{-5} rem 50 yr. committed effective dose equivalent (EDE) at approximately 10 km from the release point.
TA–16	205	Weapons Engineering Tritium Facility	The maximum dose (MEI) was calculated as 0.25 rem at 4.85-km distance. Doses are less at shorter distances due to the plume rise. The population dose is 189 person-rem within the 80.5-km (50-mile) radius.
TA–21	155	Tritium Science Test Assembly (TSTA)	Release of 200 grams of tritium oxide, resulting in population dose of 24 person-rem, and a mean MEI dose of 0.012 rem at State Road 502 (360 meters). These consequences are 25% less under the Reduced Operations Alternative.
TA–21	209	Tritium Science and Fabrication Facility	MEI dose of 0.006 rem at State Road 502 (360 meters) and 12 person-rem population dose.
TA–43	1	Health Research Laboratory	ERPG–2 and ERPG–3 distances are 0.17 and 0.1 miles (0.27 and 0.16 km) respectively. The number of people exposed to formaldehyde at greater than ERPG–2 and ERPG–3 are 11 and 6, respectively.
TA–48	1	Radiochemistry Laboratory	MEI dose from the entire building fire is 50 mrem at the Royal Crest Trailer Park. Chemical exposures at this location are less than ERPG–2.
TA–54	153, 224, 226, 229, 230, 231, 232, 283, 33, 48, 49, Pad 2	Waste Drum Preparation, and domes	Total population exposure 400 person-rem, and mean MEI of 22 rem at both White Rock and Pajarito Road.

East Jemez and Pajarito roads will evacuate another 800 cars per hour.

In a realistic scenario, evacuation of the town begins when the fire is well into the LANL site, but is impeded because of panic, accidents, and the very limited road system, including the closure of Pajarito Road. Some fraction of the population refuses to leave, and a significant number are relocated to the eastern edge of the town where there is less fuel load. Los Alamos has 11,500 residents, and White Rock has 8,000 residents. Los Alamos County estimates there are 2.4 people per family, and that 25 percent of the families will take two vehicles instead of one. It is accepted that the 6,200 LANL employees will all go home before evacuating the mesas. The 4,000 people living off the hill will take 1.25 hours to evacuate at two people per car in the absence of accidents. If all the employees go home first, the people living off of the hill may have cleared before the townsite begins. There would be 6,832 cars to leave the hill, which would take 4.3 hours. This is based on 2.4 people and the 25 percent extra vehicles. It should also be noted that up to 10 percent of the people might refuse to evacuate.

Because the differing population density as a function of time cannot be predicted, the results of the MACCS calculations must be presented as exposures to the same populations and receptors as used in the other accident analyses. Under the conservative assumptions applied in this analysis, the collective population dose from the wildfire consuming buildings is estimated to be about 625 person-rem. To this there may be added another 50 person-rem to capture the minor exposures from burning vegetation and from unidentified residual contamination in other buildings and vegetation. Most of this dose, about 75 percent, would come from the TA–54 Waste Management Complex. A population exposure of 675 person-rem would be expected to result in 0.34 excess LCFs.

Effects on Workers

All threatened workers would be evacuated prior to arrival of the fire front. Aircraft crashes with fatalities have occurred while dropping slurry on wildfires. Firefighters on the ground are at risk if they enter an area without an alternate escape route, and there have been historical fatalities from such events. However, because life safety is given first priority over protection of property at LANL, it is not likely that there will be worker fatalities. Some firefighters and other emergency personnel are likely to have significant but transient effects from smoke inhalation.

Ancillary Environmental Effects

Firewater. Firewater (water used in fighting building fires) at nonnuclear facilities is captured by outdoor containment and temporary dikes erected for fire fighting. Firewater at nuclear facilities is captured by the drain system and is sent to TA–50 for processing. Conceivably, some radioactively contaminated water could reach the outdoor environment, but would be of such small volume that it would not leave the building environs. Resultant contaminated soil would be eroded, pending the return of vegetative cover. As with other contaminated soils, the environmental and human health threat from the new contamination would be assessed and mitigated.

Loss of Protective Cover. The charred plant remains following a severe wildfire are the only immediate visual consequences. The consequences of a wildfire are diverse, continuing through time and space, and frequently having significant changes in geomorphology and biological communities and processes. LANL is perhaps unique in potential consequences, because in addition to a rich presence of biological communities and cultural remains and resources, there exists soil bearing legacy contaminants from historical operations.

Trees, grass and herbaceous cover, and forest litter are important features in stabilizing soils by: (1) reducing the velocity and impact of falling raindrops; (2) reducing the velocity of runoff, thereby encouraging infiltration and discouraging its transport by water and wind; and (3) reducing runoff quantities. Loss of vegetative cover will create a setting that can have pronounced effects on flow dynamics, soil erosion, and sediment deposition. These changes also can have significant ramifications for plant and animal communities and cultural resources.

Runoff, Soil Erosion, and Sedimentation. Without a protective ground cover, runoff quantities and velocities will be magnified, and soil erosion by water and wind will begin immediately. Contributing to this condition will be the likely formation of an ash layer that will inhibit the infiltration of runoff. Decreased infiltration will increase the quantity and velocity of surface runoff, promoting higher channel volumes and watershed discharges. These higher runoff quantities will be discharged into the Rio Grande where they will contribute to the overall floodwater storage of Cochiti Lake. Modified hydrologic conditions likely will cause some watercourses that have only rarely had sufficient flows to reach the Rio Grande to increase their frequency of discharge.

Commensurate with higher runoff quantities and velocities will be an increase in soil erosion. Sheetflow will begin transporting soil suspended by rainfall droplet impact. Both rill and gullying will begin on sloping ground surfaces with the first significant rainfall event. Higher channel volumes and velocities will promote both downward and lateral scouring of channels in the steeper portions of the watershed and sediment deposition in the lower portions. (These conditions depend on quantity of runoff discharges and resulting changes in channel hydraulics.) Headcutting will increase throughout the channel system. Delta formation will increase at the confluence of watercourses tributary to the Rio Grande, and added sediment will contribute to the depletion of the sediment reserve of Cochiti Lake.

The gradual establishment of ground cover will correspondingly retard soil erosion and a more stabilized hydrologic regime will return.

Effects on Legacy Contaminants. Active erosion processes have moved some contaminants bound to sediment from the watershed into the Rio Grande, mainly as suspended sediment and bedload sediment. Conversely, many of the remaining legacy contaminants at LANL are present in situ or have not been transported far from their origin or remain on site. Water transport is a major mechanism for the transport of contaminants both in the dissolved and suspended sediment phases. Because vegetation acts to hold soil and reduce erosion, its loss (however short term) may significantly increase the potential for erosion and the transportation of contaminants. Some water courses have only rarely had sufficient flow to reach the Rio Grande, and because of this they have become “discharge sinks” for some contaminants. Increases in runoff amounts and frequency will increase the potential to remove and transport contaminants from the ground surface and subsurface and stream channels on LANL into the Rio Grande and downstream to Cochiti Lake.

Effects on Biological Systems. Although fire is a natural part of biological systems, anthropogenic influences such as grazing, logging, and fire suppression have produced conditions that have pronounced adverse effects on forest ecosystems. Natural high-frequency, low intensity fire regimes have been replaced with low-frequency, high-intensity fires that consume a higher percentage of vegetation. As reflected in other nearby areas that have experienced severe wildfires in the past (e.g., Water Canyon, La Mesa, Dome, and Oso Complex fires), a wildfire at LANL will result in a period of disequilibrium with a reversion to early seral development and a corresponding change in animal use (Allen 1996). Fire debris, fallen trees, and needle cast will gradually begin to check erosion and develop soil conditions that will promote the establishment of grasses and herbaceous vegetation that will in turn further reduce erosion. This gradual re-establishment of ground cover will begin the dynamic process of seral progression toward a wooded or forested plant community.

A loss of forest or woodland habitat will result in a temporary loss of habitat for a broad spectrum of animals. As vegetation is re-established an altered community of animal species will follow, its composition changing with the evolution of the plant community. The pattern of burned vegetation will play a significant role in renewed wildlife use. Early plant communities of grasses and herbaceous growth can have a high biomass and species diversity as exhibited by nearby areas affected by recent wildfires. This expansion of grass and herbaceous growth could provide additional forage for the large elk population in and around LANL and contribute to existing management concerns.

Impacts on threatened and endangered species (e.g., the Mexican spotted owl) will depend on several factors such as the burn pattern, the time of day that the burn occurs, the type of fire, topography, and if nesting is occurring. Threatened and endangered species have remained or returned to nearby areas that have experienced recent burns. Some species, such as the peregrine falcon, could benefit through improved foraging habitat. Individual response to fire also will vary. Perhaps the most significant impact to threatened and endangered species precipitated by a wildfire could be the general disturbance caused by the fire fighting effort itself (e.g., fire fighting crews, aircraft, and vehicular traffic).

As discussed previously, increased runoff discharges will result in a commensurate increase in channel scouring, enlargement, and headcutting. This process and any accompanying sedimentation will have the potential to degrade or remove the limited riparian vegetation on LANL. Wetlands associated with water courses also would be affected, and perhaps several would be removed for a period of time because of changes in channel morphology. With the degradation of riparian vegetation and wetlands would be an associated reduction or loss of habitat for a variety of invertebrates, small and large mammals, amphibians, reptiles, and a diversity of birds.

Any impacts of contaminants transported to downstream riverine and lacustrine ecosystems is unknown, but there could potentially be an increase in ecological risk.

Effects on Cultural Resources. LANL is located in a region of abundant and culturally significant prehistoric and historic resources, including traditional cultural properties. As stated, fire is a normal feature of the landscape and has played and continues to play a natural role in the culture of regional communities. Because of anthropogenic influences, the character of recent fires will be different from historic fires and will affect resources differently. Also, the need to protect property and life from wildfire will necessitate measures that can affect cultural resources.

As discussed, high intensity fires can burn an appreciable amount of ground cover and accelerate erosion. Surface erosion can physically disturb surface features and confuse and distort the contextual integrity of the site. More pronounced erosion in the form of gully formation and lateral bank cutting can permanently remove site features. Also, a high intensity fire can scorch organic remains located near the ground surface, decreasing their interpretive value. Historical structures can suffer through direct incineration. Damage to these resources also can occur as a consequence of vehicular traffic and mechanical disturbance (e.g., bulldozers and fire trucks) and other soil disturbing activities connected with the firefighting effort.

Traditional cultural properties present on and adjacent to LANL include ceremonial and archaeological sites, natural features, ethno-botanical sites, artisan material sites, and subsistence features. These resources are an integral part of the landscape and almost certainly are and have been affected by natural fires. Because of the altered character of fires, these resources may be affected to a greater extent. Depending on the characteristics of these properties, they could either be permanently or temporarily affected by a wildfire and its subsequent ancillary effects (e.g., erosion).

Mitigation

The next fire season begins in April 1999. As a result of the process of this accident analysis, actions were initiated to reduce the wildfire risk to major facilities with significant radiological inventories. Specifically, considerations were given to reducing the risk to low or very low for the following facilities:

- TA–3 Building 66/451, Sigma
- TA–54 (Area G) Pads
- TA–21 Building 209, Tritium Science and Fabrication Facility (TSFF)
- TA–21 Building 155, Tritium Storage and Test Assembly (TSTA)
- TA–16 Building 205/205A, Weapons Engineering Tritium Facility (WETF).

Nevertheless, the public exposure from these specific facilities has been included in this wildfire analysis. With the completion of these actions, the population dose from site-wide wildfire would be reduced from an estimated 675 person-rem to 50 person-rem, with associated 0.25 excess LCF. In addition, although no credit is taken for it in this analysis, the long-term environmental restoration of contaminated sites will reduce airborne nuclides suspended by vegetation fires over those sites.

There also is an ongoing, interagency, collaborative program to reduce the threat of catastrophic wildfire from occurring at LANL and the townsite by thinning and removing vegetation at the perimeter and in the surrounding Santa Fe National Forest and Bandelier National Monument. This will reduce the frequency and intensity of wildfires that could impinge on LANL.

Uncertainties

The frequency of wildfire impinging on LANL was estimated as 0.1 per year under the current fuel conditions in the surrounding forest and perimeter. This frequency includes wildfires approaching from the north through west and south. When fire enters LANL or originates from within LANL, there are numerous credible scenarios, most of which consume less of the LANL area than is covered in this analysis. Specifically, this analysis presumes that the fire jumps the Pajarito Road or any other established control line, spots or otherwise burns into all contaminated canyons, and successfully climbs canyon walls to ignite combustible buildings with moderate and higher wildfire vulnerability. The frequency of such a site-wide fire is surely less than 0.1 per year. The consequences of a complete burning of the western portion of LANL are presented in accord with the conservative nature of this SWEIS as a whole.

The plume rise calculated by OBODM in the canyon fires is likely to be much less than that which would actually occur resulting in lower doses at a distance of 330 and 3,300 feet (100 and 1,000 meters). This analysis used only the heat content of the fuel over the contaminated area; whereas, there is much fuel to the sides of the fire, and the combined heat would loft the plume thousands of feet. The observed convection columns in the past major forest fires would carry most contaminants far above the breathing zone of downwind individuals.

The wind speed used for dispersion of airborne material from the contaminated site fires was only 2 meters per second, which is probably less than would occur during a wildfire. The doses are inversely proportional to the wind speed, such that if the observed wind were 6 meters per second, the dose would be 1/3 that calculated.

The fraction of the suspended contaminant that is respirable (less than 10 micrometers equivalent aerodynamic diameter) is unknown. According to Section D.5 of the DARHT EIS, the uranium in the soil is not all respirable. The particle size of the airborne soil contamination is likely to be large because the contaminants will be attached to soil particles preceeding the fire and to soil and smoke particles in the plume. Because the airborne contaminant particle size is unknown, an RF of 1.0 is assumed. This is very conservative.

The White Rock and Santa Fe population is included in the MACCS calculations. The additional MACCS calculations for WETF and Sigma made for this wildfire analysis used the winds observed June 7 to 10, 1998, which are toward the Los Alamos townsite; whereas, the previous calculations for the other facilities used representative annual meteorology from 1995 (as described in section G.2.4). Because population is not evenly distributed about these sources, there would be a difference in the integrated population dose (i.e., in the person-rem) depending upon the meteorology used. Because the source inventories at the buildings vulnerable to wildfire do not vary significantly among alternatives, this does not affect the decision. (The inventory at TSTA is reduced by 25 percent under the Reduced Operations Alternative.)

The model calculations for dispersion of the plumes, for canyon sources several and more kilometers long, are most uncertain. The source was input as a volume having the dimensions of the width and length of the contaminated area, oriented along the axis of the wind direction. Differences in concentrations downwind are noted if the source is entered as a volume source versus a line source. The model also objects to a burning time longer than 60 minutes, and was manipulated into accepting these extensively long volumes and longer burn times. The 60-minute limitation in the model is likely intended to prevent the user from exceeding the bounds of experimental data, most of which is for 10 to 30 minute releases. There are no field experiment data to which the canyon results can be compared. However uncertain, the radiological exposures predicted for the canyon fires are orders of magnitude less than the 100 mrem annual limit for public exposure from routine releases.

It has been estimated that there would be 50 person-rem from burning of buildings with residual contamination and from identified and unidentified contaminated soil/vegetation areas. This is a number not supported or disputed by hard data, and is believed to be very conservative.

There are no release fractions available for radionuclides other than plutonium and uranium. For consistency only, the ARF x RF of 4×10^{-4} for uranium was also used for plutonium, americium, and cesium in contaminated soils, which is conservative for plutonium by a factor of 7, and therefore, overestimates the bounding doses for mixed nuclides and TRU in Table G.5.4.4–2 by this factor.

There is no ready evidence that burning of the vegetation over the firing sites would produce detectable airborne DU. The U.S. Army tested DU projectiles at the Jefferson Proving Ground, releasing 50 metric tonnes of uranium in a 4 year period, of which 45.5 metric tonnes were not recovered from the area. Special samples showed that most of the DU was on or near the surface. The vegetative undergrowth was regularly controlled through burning, at which time high volume particulate air samples were collected. Analyses of the air samples did not detect any DU (Abbott 1988). For DU munitions in an intense wood-fuel oil fire burning for 2 hours, no airborne DU was collected in the air samplers at various distances out to 328 yards (100 meters), and 0.01 of residual oxides was in the respirable size range (DOE 1994d).

The MEI and population doses do not take credit for sheltering in vehicles or buildings, which will easily reduce doses to 1/2 to 1/20 of that outdoors (Engelmann 1990, Engelmann et al. 1991). It should be noted that airborne contamination will be in the smoke, which people are inclined to avoid.

About 400 person-rem, or 75 percent of the total population exposure of 675 person-rem, results from a wildfire at TA–54. The results from RAD–08, an aircraft crash-initiated fire at TA–54, were used for the wildfire. The two fires would be quire different, one entailing aircraft fuel that will challenge waste containers. At present, the combustible loading within the dome structures is small, so that RAD–08 results very conservatively bound the consequences of a wildfire at TA–54.

Another 189 person-rem results from total release of the tritium inventory at WETF, including 1,260 grams in storage, which is assumed to bound an increased administrative limit that may be established. The storage containers are resistant to fire, but have been assumed to release their entire content in tritiated water form, in accord with the highly conservative nature of this analysis.

G.5.5 Chemical Accidents

G.5.5.1 *CHEM–01, Single Cylinder Release of Chlorine from Potable Water Chlorinator*

General Scenario Description

Accident scenario CHEM–01 postulates a chlorine gas leak from a single cylinder at a potable water chlorination station. The accident is initiated by equipment failure or human error during chlorine cylinder replacement or maintenance activities at the chlorinator station. Two, 150-pound chlorine cylinders are connected to the injector system, which adds a small amount of chlorine to the potable water system for purification purposes.

The scenario is modeled as occurring at TA–00–1109, which is a site in the town of Los Alamos north of the high school. This location is one of nine chlorinator sites located around LANL and the town; the other locations are TA–00–1110, TA–00–1113, TA–00–1114, TA–16–560, TA–33–200, TA–54–1008, TA–72–3, and TA–73–9. TA–00–1109 was selected as the modeling location based on its proximity to residential housing and special populations, and provides an upper bound estimate of the potential impacts to the public. (It should be noted that a study is being conducted by LANL to evaluate the conversion of the chlorinator systems from a gaseous chlorine system to a less hazardous MIOX system that hydrolyzes brine to produce chlorine on site. In addition, negotiations are in progress that could lead to the chlorinator system being turned over to Los Alamos County.)

CHEM–01 Release Mechanisms

Chlorine usage has been estimated for the four SWEIS alternatives, with an average of seven to nine cylinders used per year at each of the potable water chlorinator stations. The chlorinator system at TA–00–1109 is a sweetener station that actually uses only two to three cylinders per year. Hence, it is conservative to model the station use rate at seven to nine cylinders per year, depending on the alternative.

Three leakage rates were defined for this event. The smallest leak is essentially a pin-hole leak that would result from random equipment failures or human errors. The next leak considered as a valve failure, which would open a 0.25-inch (0.64-centimeter) diameter hole in the cylinder pressure boundary. Finally, a random cylinder rupture was defined that would instantaneously depressurize the cylinder.

No Action Alternative Frequency Analysis

The frequency of these endpoints was calculated separately for hardware and human error initiating events. Random cylinder failure (leak or rupture), as well as failures of the packing, the pressure gage, or the vacuum regulator can result in a chlorine release. The equipment failure contribution to this scenario is quantified as follows:

$$F_{EQP} = (F_{RAND\text{-}LEAK}) + (F_{RAND\text{-}RUPT})$$

where:

F_{EQP} = Annual frequency of the scenario due to equipment failure

$F_{RAND\text{-}LEAK}$ = Frequency of random failure resulting in cylinder leakage

$F_{RAND\text{-}RUPT}$ = Frequency of random failure resulting in cylinder rupture

These terms are all random events with a general equation as follows:

F = (rate/hr) x (8,760 hr/yr) x (number of items)

These values are as follows:

$F_{RAN\text{-}LEAK}$ = (2 x 10^{-8}/hr) x (8,760 hr/yr) x (4) = 7 x 10^{-4}/yr (LARGE LEAK); for factor of 20 difference from rupture (Mahn et al. 1995 and LANL 1995c)

$F_{RAND\text{-}RUPT}$ = (1 x 10^{-9}/hr) x (8,760 hr/yr) x (4) = 3.5 x 10^{-5}/yr (RUPTURE) (Mahn et al. 1995)

The total equipment failure contribution to CHEM–01 can be evaluated as follows:

$$F_{EQP} = F_{RAND\text{-}LEAK} + F_{RAND\text{-}RUPT}$$

$$F_{EQP} = (7 \times 10^{-4}) + (3.5 \times 10^{-5})$$

$$F_{EQP} = 7 \times 10^{-4}\text{/yr (LARGE LEAK)}$$

$$F_{EQP} = 3.5 \times 10^{-5}\text{/yr (RUPTURE)}$$

The human error contribution to this scenario is quantified as follows:

$$F_{HEP} = H_{VALVE} + H_{LEAK}$$

where:

F_{HEP} = Annual frequency of human error-induced chlorine release

H_{VALVE} = Human error leading to chlorine tank valve failure (LARGE LEAK)

H_{LEAK} = Human error leading to chlorine leak (SMALL LEAK)

A large leak due to valve failure would require human error in cylinder handling such that a chlorine cylinder with the valve cap removed is dropped, striking the valve and causing the valve to shear off. Small leaks could be due to a variety of causes, such as failure to follow cylinder changeout procedures resulting in a leak at the cylinder valve packing, the injector connection, tubing, or the V-notch assembly.

H_{VALVE} is related to the number of times per year that a full chlorine cylinder is removed from storage, has its valve cap removed, and then is placed into operation or into standby. Estimates of chlorine consumption in 150-pound cylinders have been made for all four alternatives (Barr 1997).

It is assumed that chlorine cylinder usage is averaged out over the nine potable water chlorinators. The number of chlorine cylinders changed out annually is eight for the No Action and Greener Alternatives, nine for the Expanded Operations Alternative, and seven for the Reduced Operations Alternative.

The basic human error rate is estimated as 0.003 per demand (Swain and Guttmann 1983). Considering that personnel performing chlorine cylinder operations are aware of the hazards involved, that the hazard is very direct, and it is therefore reasonable to assume that extra caution is employed in the operation, and that the changeout process is governed by a written procedure that is required to be used, this value was reduced by a factor of 50 to 6 x 10^{-5} per demand. (The derivation of the factor of 50 is based on the human error probability for checking the status of equipment under normal conditions and the probability for checking the status of equipment when the status affects one's safety [Swain and Guttmann 1983].) No recovery probability is assessed because once the cylinder is dropped there is no opportunity to recover the situation. For the No Action Alternative, the frequency of human error leading to a large leak as a result of valve failure is 8 x (6 x 10^{-5}), or 4.8 x 10^{-4} per year.

The human error leading to a leak is assessed based on recent experience with cylinder changeout. One leak has occurred in the past 5 years. With nine chlorinators changing out an average of eight cylinders per year, this is one leak in the change out of 9 x 8 x 5, or 360 cylinders, or a conditional probability of a leak of once per 360 changeouts, or 2.8 x 10^{-3} per changeout. With eight changeouts per year, this is a frequency of 2.2 x 10^{-2} per year.

Based on the above evaluation, the following frequencies are identified for the No Action Alternative:

- Rupture (large leak rate, complete release in less than 60 seconds; to be calculated) 3.5 x 10^{-5} per year (random rupture)
- Large Leak (1/4-inch hole corresponding to valve size) 1.2 x 10^{-3} per year = 4.8 x 10^{-4} per year (human error, dropped cylinder) + 7 x 10^{-4} per year (random leak)
- Small Leak (pin-hole type leak, rate to be calculated) 2.2 x 10^{-2} per year (human error, cylinder changeout/maintenance)

Expanded Operations Alternative Frequency Analysis

The Expanded Operations Alternative does not alter the configuration of the chlorinator system. The rupture frequency and the small leak frequencies will remain the same. The large leak frequency increases somewhat because the number of cylinders changed out annually increases from eight to nine. This results in a human error contribution of 9 x (6 x 10^{-5}) = 5.4 x 10^{-4}, plus the random leak rate of 7 x 10^{-4} per year, yielding a large leak rate of (5.4 x 10^{-4}) + (7 x 10^{-4}) = 1.2 x 10^{-3} per year.

Reduced Operations Alternative Frequency Analysis

The Reduced Operations Alternative does not alter the configuration of the chlorinator system. The rupture frequency and the small leak frequencies will remain the same. The large leak frequency decreases somewhat because the number of cylinders changed out annually decreases from eight to seven. This results in a human error contribution of 7 x (6 x 10^{-5}) = 4.2 x 10^{-4}, plus the random leak rate of 7 x 10^{-4} per year, yielding a large leak rate of (4.2 x 10^{-4}) + (7 x 10^{-4}) = 1.1 x 10^{-3} per year.

Greener Alternative Frequency Analysis

The Greener Alternative does not alter the configuration of the chlorinator system; all release frequencies are the same because the cylinder changeout rate is the same. The frequencies of occurrence for CHEM–01 are considered to be bounding and conservatively take no credit for the frequency of time that some of the chlorine cylinders stored in the building may be empty.

Source Term Calculations

The initial source term for the postulated accident equals the contents of one filled chlorine cylinder (150 pounds). Due to the physical form of the hazardous material (gas), there is no suspension source term contribution to the release. Because the cylinder size and system configuration do not vary across the alternatives, the source terms are the same across the alternatives. In all three cases (rupture, large leak, and small leak), the release is modeled as a ground level release. This is conservative because the release, especially in the case of smaller leak rates, could be released via the building exhaust system, which would result in an elevated release.

The smallest size hole with which the ALOHA™ code can perform release calculations is 0.0394 inch (0.1 centimeter) in diameter. Because this release occurs from a building, in accordance with EPA guidance the release rates are multiplied by 0.55 to correct for mixing within the building. For winter and summer conditions, this results in release rates from the building of 0.122 pound per minute and 0.181 pound per minute, respectively. Total releases within an hour total only 4 and 6 pounds of chlorine for winter and summer conditions, respectively.

For the large leak scenario, a release rate was estimated by conservatively assuming a direct release of the cylinder contents, and the same 0.55 in-building factor was applied, yielding a release rate of 8.25 pounds per minute for18.2 minutes.

Uncertainties and Sensitivities Affecting the Source Term for CHEM–01

Not all chlorine cylinders that are dropped and result in valve failure would release 150 pounds of chlorine (some would be empty or nearly so). Random failure (rupture) of a chlorine cylinder could potentially cause failure of one or more adjacent cylinders. The source term estimates above do not consider such factors. To bound the possible consequences of a process-related chlorine release from the potable water chlorination system, the assumption is made that the cylinder is full and that the release cannot be terminated once it starts. Although this is a conservative assumption, it is consistent with the approach taken in the TA–55–4 SAR (LANL 1996k) for a process-related release from a chlorine system that also uses 150-pound cylinders.

Consequences of CHEM–01 for Facility Workers and the Public

The consequences of CHEM–01 are presented separately for workers and the public. For workers, the following consequences are identified.

For the cylinder rupture accident, the likelihood of a worker being present is very low (the failure happens at random, rather than as a result of worker activity). Accordingly, no worker consequences would be expected under most conditions for cylinder rupture because workers would be present at the facility for a limited number of hours per month. Any workers present in the building would likely be killed due to the very high concentrations of chlorine that would result from cylinder rupture, as well as from the lack of time to escape from the immediate area before potentially lethal exposures would occur. Death to workers inside the building could also occur as a consequence of missiles (flying debris) generated when the cylinder ruptures.

For the large leak scenario, the workers present in the building (for the nonrandom failure part of the term) could be killed due to the high chlorine concentration in the building and/or the possibility of being struck by a missile (either the cylinder or the valve).

For the small leak scenario, injury seems to be a more likely outcome than fatality for facility workers. This is borne out by operating experience.

The public consequences for the small leak scenario are negligible (no ERPG–2 or ERPG–3 concentrations beyond 100 yards [92 meters]) regardless of the time of day, time of year, and even considering very adverse dispersion leading to a very stable, nonmeandering plume.

If the direction of the plume were to remain constant for the small leak scenario, nearby residents might detect the chlorine release by odor; however, even the ERPG–1 value of 1 parts per million would not be reached outside 100 yards (92 meters) from the facility under a conservative daytime dispersion condition (2.8 meters per second wind, Stability Class C). Under adverse (stable atmosphere) dispersion, the ERPG–1 distance could extend as far as 236 yards (216 meters). Given these results, no detailed quantification of the small leak scenario is carried forward.

For the large leak rupture scenarios, the release rate is of course much greater. For the large leak scenario, equivalent to a ruptured cylinder valve, the release rate is 2.2 to 3.8 pounds per minute (variable depending on time of year). Under adverse (stable atmosphere) dispersion, the ERPG–2 distance is 0.6 mile (1 kilometer), while the ERPG–3 distance is 0.2 mile (0.3 kilometer). Under conservative daytime dispersion, the ERPG–2 distance varies from 0.16 to 0.26 mile (0.26 to 0.42 kilometer), while the ERPG–3 distance varies from 0.06 to 0.09 mile (0.1 to 0.14 kilometer). The average number of people exposed at concentrations greater than ERPG–2 and ERPG–3 under adverse dispersion is 81 and 30, respectively, and for ERPG–2 and ERPG–3 under conservative daytime dispersion about 43 and 12, respectively.

For the rupture scenario, ERPG–2 concentrations reach a distance of about 1,600 yards (1,464 meters) under adverse dispersion (stable atmosphere) and a distance of about 500 to 700 yards (458 to 641 meters) under conservative daytime dispersion. ERPG–3 distances are about 450 yards (412 meters) under adverse dispersion and about 200 to 250 yards (183 to 229 meters) under conservative daytime dispersion. The average number of exposed people exposed to concentrations greater than ERPG–2 and ERPG–3 under adverse dispersion is 226 and 180, respectively, and about 53 and 12, respectively, under conservative daytime dispersion. A summary of CHEM–01 results is presented in Table G.5.5.1–1.

G.5.5.2 *CHEM–02, Multiple Cylinder Release of Chlorine from Gas Plant*

General Scenario Description

Scenario CHEM–02 involves a multiple-cylinder release of chlorine from TA–3–476. This building is an all-weather, prefabricated, "Apache" all-metal storage shed that is used to store chlorine cylinders (and other hazardous gas cylinders) prior to distribution to end users at LANL. TA–3–476 is located at the northwest corner of the Gas Plant (the main facility at the Gas Plant is TA–3–170), which is located along Eniwetok Road near the Sigma Facility (TA–3–66). The storage shed, which has an open metal grate at the bottom, rests on asphalt.

In addition to chlorine, other extremely toxic gases that have in the past been temporarily stored at TA–3–476 include phosgene, arsine, phosphine, and fluorine. Such gases are typically present 1 day or less per year per gas. Some quantity of chlorine is present essentially all the time. The release of the largest single container of these gases has been modeled in the Safety Assessment under adverse dispersion conditions (Class F stability, wind speed of 3.3 feet [1 meter] per second) and compared with a 150-pound chlorine cylinder release. The distances to which ERPG–2 and ERPG–3 exposures could be experienced were the largest for the chlorine cylinder release.

The frequency of release of gases other than chlorine would be directly proportional to the conditional probability of their presence at the facility. Accordingly, it has been determined that the risk of a release of chlorine from TA–3–476 bounds the risks of release of other toxic gases both in frequency of occurrence and in the consequences of the release.

The CHEM–02 accident scenario involves a release of chlorine gas, which is conservatively assumed (with respect to exposure at short distances) to occur at ground level, followed by dispersal of the gas downwind. The release is also conservatively modeled as involving simultaneous release from multiple cylinders. In fact, the cylinders may not all release at the same time, in which case the downwind concentrations would be less, and there would be less chance of exceeding the thresholds for health effects.

Properties of Chlorine Gas

Chlorine is a greenish-yellow gas or liquid. Chlorine is extremely irritating to the mucous membranes of the eyes and respiratory tract at a concentration of 3 parts per million. A concentration of 3.5 parts per million is detectable by odor. A concentration of 15 parts per million causes immediate irritation of the throat. Concentrations of 50 parts per million are dangerous for even short exposures, and concentrations of 1,000 parts per million may be fatal even when the exposure is brief (Lewis 1993). The ERPG–1, –2, and –3 concentrations are 1, 3, and 20 parts per million, respectively (Craig 1996). The pressure in a 150-pound chlorine cylinder is 0.588 MPa (85.3 psig) at a temperature of 70°F (21°C) (MGP 1997). Cylinders containing chlorine are equipped with a fusible metal plug with a melting temperature of 165°F (73.9°C) (Braker and Mossman 1980). In the event of a fire that exceeds this temperature, the fusible plug will melt, permitting the chlorine to escape but preventing the cylinder from catastrophically failing due to overpressure. Chemical reactions of chlorine of potential interest to this scenario include the reaction with carbon monoxide to form phosgene (carbonyl chloride, CCl2O, a colorless poison gas) (Braker and Mossman 1980), and the reaction with ammonia causing an explosion (Lewis 1993).

Properties of a Heavy Gas

The release of chlorine from a pressurized cylinder will consist of a combination of droplets and vapor constituting a heavy, cold cloud full of small droplets that remain airborne and travel significant distances. The continuing evaporation of these droplets along the plume path virtually renews the strength of the cloud as it travels and keeps it cool and heavier than the ambient air. This has significant effects on the dispersion, and the standard Gaussian plume models are inappropriate; "heavy gas" models such as DEGADIS and SLAB must be used instead. The cloud can persist for substantially longer times than the spill duration, and plume travel time can be substantially longer than would be expected from the wind speed. When the concentration of the chlorine falls to a value such that the cloud density is similar to that of the air, it no longer acts independently of the air as a heavy gas, but behaves as a passive tracer. The concentration at which this occurs depends upon the wind speed and height of the cloud (which in turn depends upon the size of the release). When the wind is 3.3 feet per second (1 meter per second) and the chlorine cloud is 33 feet (10 meters) high, the change from heavy gas to passive behavior occurs at about 280 parts per million. This is substantially greater than the ERPG–3 of 20 parts per million and produces serious health effects. For this reason, protection from a chlorine release is not assured by intervening canyons.

CHEM–02 Release Mechanisms

Three potential release mechanisms were identified and subjected to detailed analysis. Release by direct impact of a vehicle on the stored cylinders was screened out based on the presence of vehicle barriers in front of and to the sides of the storage shed, the inability of a vehicle to approach the shed from behind (an arroyo is located behind the shed), and the administrative controls on speed limits at the Gas Plant (along with the DOT training and LANL-specific training of truck drivers at the plant). Two other release mechanisms were considered for their contribution to the frequency of CHEM–02: (1) a truck fuel fire, resulting in failure of the chlorine cylinders; and (2) the impact of an aircraft on nearby hydrogen tube trailers, resulting in failure of multiple chlorine cylinders due to overpressure, impact by missiles (shrapnel created by the detonation of hydrogen tubes upon impact by the aircraft), or fire.

This accident was not analyzed in the Gas Plant Safety Assessment (LANL 1994b). The safety assessment (SA) screened all multiple cylinder release scenarios as being incredible (i.e., having frequencies less than 10^{-6} per year). The most severe scenario analyzed in the SA was a single cylinder release of chlorine (see CHEM–03, section G.5.1.6). The SA concluded that the installation of the vehicle barrier around TA–3–476 eliminated the possibility of a multiple cylinder release. While this appears to be a valid conclusion insofar as direct vehicular impact with the chlorine cylinders is concerned, it is not clear that the SA considered a fuel fire for which the vehicle barriers would be ineffective.

No Action Alternative Frequency Analysis

The fuel fire and aircraft crash contributors are analyzed separately. In the case of a fuel fire, a truck accident near TA–3–476, or one impacting the vehicle barrier around TA–3–476, could result in a failure of the truck fuel system or the fuel tank(s), resulting in a spill of diesel fuel. Second, a truck parked near TA–3–476 could experience a fuel system leak or fuel tank leak due to causes unrelated to a vehicle accident. In either case, once a fuel leak occurs, ignition of the spilled fuel would lead to a fire that, if it is close enough to TA–3–476 and it is not suppressed, would result in damage to the chlorine cylinders and a release of chlorine to the environment.

There are no automatic means of fire detection or fire suppression installed at TA–3–476, although there is a fire hydrant located within 164 feet (50 meters) of TA–3–476 where fire hoses could obtain water for fighting the fire. Manual fire fighting equipment (extinguishers) is provided at TA–3–170. The response time of a fire brigade to TA–3–476 is estimated at 2 to 3 minutes; the fire station at TA–3–41 is within a kilometer of TA–3–476.

There are no physical barriers present that are capable of precluding a fire from reaching TA–3–476. There are concrete-filled metal tubes installed at the front of TA–3–476 to prevent the impact of a vehicle on the storage shed. While the barriers will essentially preclude direct vehicular impact with the cylinders, the barriers will have no affect on the propagation of a fuel fire (which could result from a ruptured fuel line/fuel tank as a consequence of impact of a vehicle with the vehicle barriers).

The frequency of the fuel leak and fire contributor accident can be estimated using the following equation:

$$F_{FIRE} = N_{SHIPMENTS} \text{ x } L \text{ x } F$$

where:

F_{FIRE} = Frequency of a fire at TA–3–476

$N_{SHIPMENTS}$ = Number of shipments to or from TA–3–476 per year

L = Fuel leak rate per shipment

F = Conditional probability of fire given a fuel leak and subsequent release of chlorine

The frequency of a fuel system leak or fuel tank leak and a resulting fire is assessed for TA–3–476 based on methods and data contained in the TA–54, Area G Hazard Analysis (LANL 1995g) and the evaluation of TRU waste transportation by H&R Technical Associates (Rhyne 1994). The annual frequency of a fuel leak was assessed at 0.1 per year in the TA–54 hazard analysis

(LANL 1995g). Embedded in this estimate is 78 trips per year of trucks to the facility. Thus, on a per trip basis, the likelihood of a fuel leak is 0.1/78, or 1.3 x 10^{-3} per trip.

The TA–54 hazard analysis (LANL 1995 through 1997) cites data from Rhyne 1994 to the effect that the conditional probability of a fire given a fuel leak is 4.7 x 10^{-3} per fuel leak. Although the direct applicability of this value is open to interpretation, the value is used in CHEM–02, RAD–01, and RAD–07 because no other comparable value could be identified and because DOE believes the value to be conservative.

The TA–54 hazard analysis recommended an additional frequency reduction by a factor of ten compared with the H&R evaluation due to the fuel being diesel (LANL 1995g). However, the H&R evaluation already takes into account the fact that the transport vehicle is a flatbed truck, which is a diesel fuel vehicle (Rhyne 1994). Accordingly, this additional factor of ten reduction in conditional probability was not employed here.

Site-wide usage of chlorine has been estimated across the alternatives in Table G.5.5.2–1. The number of shipments to or from TA–3–476 per year for the No Action Alternative is estimated based on the sum of shipments from the chlorine supplier to TA–3–476 and shipments from TA–3–476 to the potable water chlorination stations in and around LANL. During the walkdown of TA–3–476, it was stated that there were two shipments per year from the chlorine supplier. However, this information is inconsistent with the number of 150-pound chlorine cylinders estimated to be used annually.

The data in Table G.5.5.2–1 was interpreted by dividing the 150-pound cylinder usage by 150 pounds to obtain the approximate number of cylinders used annually. This value is shown in the last row of Table G.5.5.2–1. Because only ten full chlorine cylinders are permitted to be in TA–3–476 at any one time (LANL 1997b), the number of trips was approximated by dividing the number of cylinders used annually by ten (the number of cylinders allowed to be at TA–3–476). The number of supplier shipments is thus seven per year for all alternatives except Expanded Operations, where the number of supplier shipments is eight.

The number of shipments from TA–3–476 to potable water chlorinators is 14 per year (based on shipments of no more than 5 cylinders at a time and a total of 70 cylinders needed per year). The total number of shipments is therefore 7 plus 14, or 21.

The frequency equation can be solved as follows for the No Action Alternative:

$$F_{FIRE} = N_{SHIPMENTS} \text{ x L x F}$$

$$F_{FIRE} = 21 \text{ x } (1.3 \text{ x } 10^{-3}) \text{ x } (4.7 \text{ x } 10^{-3})$$

$$F_{FIRE} = 1.3 \text{ x } 10^{-4}\text{/yr}$$

As noted above, fuel fires also can occur as a result of a truck accident near TA–3–476 or as a result of an impact of a vehicle with the vehicle barrier immediately in front of TA–3–476. The general accident rate for highway traffic is 1 x 10^{-6} per mile (Fenner 1996). Data on which the RADTRAN transportation accident code is based show that only 29 percent of all accidents occur at speeds of 20 miles per hour or less (Clarke 1976), which is what would be expected at the Gas Plant because the speed limit is 15 miles per hour (allowing for some margin over this value, 20 miles per hour was selected as a quantification basis). Thus, the accident rate should be (1 x 10^{-6}) x 0.29 = 2.9 x 10^{-7} per mile. Even if the distance from the Gas Plant security gate to TA–3–476 is used for quantification, this is a distance of approximately 220 feet (67 meters) or 0.042 miles. The accident rate per trip is thus 21 trips/yr x 0.042 miles/trip x (2.9 x 10^{-7} accidents/mile) = 2.6 x 10^{-7} accidents per year. Even allowing that there are trips near

TA–3–476 not involving chlorine shipments, there would have to be thousands of such shipments before this contributor would begin to compete probabilistically with the fuel leak/ fire scenario quantified above. Moreover, each shipment would have to pass sufficiently near TA–3–476 such that the fire, if it occurred, actually reached the chlorine cylinders stored in that building. Accordingly, this potential accident contributor was screened out.

Evaluation of Hydrogen Tube Trailer Failure

During the physical inspection (walkdown) of the Gas Plant and during subsequent visual spot checks, there have been four or five hydrogen tube trailers parked within 164 feet (50 meters) of TA–3–476. Gas Plant management states that typically half of the trailers are empty and half are full (Lovato and Nielsen 1997). The trailers are typically located within less than 164 feet (50 meters) of TA–3–476.

In the event of a catastrophic tube trailer failure (rupture of tube or tubes, detonation of hydrogen), there are no physical barriers that could preclude overpressure or missile impact from reaching TA–3–476. The outer shell of TA–3–476 is simply sheet metal, which would offer very little resistance.

A tube on a hydrogen tube trailer failed catastrophically at TA–3–170 in June 1981. There was no effect on TA–3–476 as a result of that accident, and the tube failure did not propagate to the entire tube trailer. While the specific scenario that occurred in June 1981 is no longer considered to be credible (the process that caused the accident is no longer performed at the facility), the hydrogen tubes could fail due to other causes.

The tube trailers are DOT Type 3AA trailers with 38 tubes per trailer. The trailers are 22 feet (6.7 meters) long. Each tube trailer holds 50,000 standard cubic feet of hydrogen gas (261.37 pounds of hydrogen). In order to evaluate the consequences of the catastrophic failure of an entire tube trailer, a simple TNT equivalent calculation was performed. In accordance with standard practice involving calculations of explosive yield for design purposes, a 20 percent safety factor was applied to the calculation. Assuming 100 percent explosive yield is grossly conservative. In accordance with recommendations by the American Institute of Chemical Engineers, a 15 percent conversion factor was used (AICE 1994). The estimated explosive yield (in TNT equivalent) was calculated to be about 965 pounds. This amount of TNT was found to be insufficient for a 10-psi overpressure to reach TA–3–476, and it was concluded that random failure of a single tube trailer could not cause a chlorine release.

Calculations of aircraft crash frequency have been performed according to the methodology in DOE Standard 3014-96 (DOE 1996c). The width of the “target” was increased to account for the chlorine storage shed itself (TA–3–476) as well as the hydrogen tube trailers. This was done to account for the possibility that the aircraft would impact the tube trailers, causing a detonation of one or more tube trailers. The resulting crash frequency was calculated to be 2.0×10^{-7} per year.

The frequency of occurrence for CHEM–02 is the sum of the frequency of the contributing means of occurrence:

$$F_{TOTAL} = F_{FIRE} + F_{AIR}$$

where:

F_{TOTAL} = Total scenario frequency

F_{FIRE} = Frequency from vehicle fires

F_{AIR} = Frequency from aircraft crash

This equation can be evaluated as follows:

$$F_{TOTAL} = F_{FIRE} + F_{AIR}$$

$$= (1.3 \times 10^{-4}) + (2.0 \times 10^{-7})$$

$$= 1.3 \times 10^{-4} \text{ per year}$$

Expanded Operations Alternative Frequency Estimate

The only change in circumstances affecting the frequency of CHEM–02 compared with the No Action Alternative is the frequency of shipments to or from TA–3–476 for the vehicle fuel fire scenario. For the Expanded Operations Alternative, the number of shipments increases from 14 to 16 per year due to a higher rate of chlorine consumption for potable water use. In addition, the number of shipments from the chlorine supplier increases from seven to eight per year. The total number of shipments is thus 24, and the frequency of the vehicle fuel fire contributor can be estimated as follows:

$$F_{FIRE} = N_{SHIPMENTS} \times L \times F$$

$$F_{FIRE} = 24 \times (1.3 \times 10^{-3}) \times (4.7 \times 10^{-3})$$

$$F_{FIRE} = 1.5 \times 10^{-4}$$

The summed frequency for all contributors becomes:

$$F_{TOTAL} = F_{FIRE} + F_{AIR}$$

$$F_{TOTAL} = (1.5 \times 10^{-4}) + (1.3 \times 10^{-6})$$

$$F_{TOTAL} = 1.5 \times 10^{-4} \text{ per year}$$

Reduced Operations Alternative Frequency Calculation

The only change in circumstances affecting the frequency of CHEM–02 compared with the No Action Alternative is the frequency of shipments to or from TA–3–476 for the vehicle fuel fire scenario. For the Reduced Operations Alternative, the number of shipments decreases from 16 to 13 per year due to a higher rate of chlorine consumption or potable water use. The number of shipments inbound from the chlorine supplier remains at seven. Thus, the frequency of the vehicle fuel fire contributor can be estimated as follows:

$$F_{FIRE} = N_{SHIPMENTS} \times L \times F$$

$$= 20 \times (1.3 \times 10^{-3}) \times (4.7 \times 10^{-3})$$

$$= 1.2 \times 10^{-4}$$

The summed frequency for all contributors becomes:

$$F_{TOTAL} = F_{FIRE} + F_{AIR}$$

$$= (1.2 \times 10^{-4}) + (2.0 \times 10^{-7})$$

$$= 1.2 \times 10^{-4} \text{ per year}$$

Greener Alternative Frequency Calculation

The frequency of shipments to or from TA–3–476 is the same for the Greener Alternative as it is for the No Action Alternative. Thus, the summed frequency of all contributors of 1.3×10^{-4} per year applies to the Greener Alternative as well.

Uncertainties and Sensitivities Affecting the Frequency of CHEM–02

The accident frequency calculations reported above do not account for the possible suppression of the fire by Gas Plant personnel or the fire department (TA–3–41) prior to the failure of the chlorine cylinders. Thus, the frequencies calculated above for the fuel fire contributor to the accident frequency represent overestimates, but given the reporting time for the fire brigade (2 to 3 minutes) and the low melting temperature of the fusible plugs on the chlorine cylinders (165°F [73.9°C]), this conservatism is not considered to be substantial.

The frequency calculations for the fuel fire contributor are sensitive to the inferred rate of fuel failures per shipment (to or from the facility) and to the conditional probability of a fire given a fuel leak. The likelihood of a fire given a fuel leak is based on vehicle accident data that include vehicle speeds of up to highway speeds. In contrast, the speed of vehicles around the Gas Plant is limited to much lower speeds. Because it would seem reasonable to assume that the likelihood of a fuel leak given an accident bears some relationship to the speed of impact (or overturning), the conditional probability of a fire given a fuel leak may be unduly pessimistic. Because an alternative value could not be identified, this admittedly pessimistic value was used in the calculations.

Source Term Calculations

The administrative limit on the number of full chlorine cylinders that can be located at TA–3–476 is eight cylinders. This limit can be exceeded for a maximum of three days by procedure on a temporary basis (LANL 1997b and Lovato and Nielsen 1997). Note that a number of cylinders in excess of ten would bring the total chlorine inventory in TA–3–476 to over 1,500 pounds. Under OSHA Standard 1910.119, Appendix A, 1,500 pounds or more of chlorine are considered to present a potential for a catastrophic event. Therefore, consequence estimates have been prepared using 1,500 pounds of chlorine. This quantity will be conservative by at least 300 pounds under most conditions. This source term is used across all alternatives.

The release was modeled as a direct release, with a constant release rate for 10 minutes based on sensitivity calculations and discussions with the code authors. The release is modeled as originating with a single cylinder that numerically represents the effective release rate of ten, 150-pound cylinders. The release is assumed to occur as a result of the melting of fusible plugs on the cylinder, which melt at 165°F (73.9°C).

Uncertainties and Sensitivities Affecting the Source Term for CHEM–02

The assumption of a ground level release is conservative with respect to chlorine gas concentrations close to TA–3–476 (such as at the TA–3 administrative complex). Indeed, the assumption of a ground level release is not realistic because the release is caused by a fire, whose heat would elevate the plume above ground level. A ground level release will produce higher concentrations at breathing level than the expected elevated release.

Consequences of CHEM–02 for Facility Workers and the Public

Workers at TA–3–170 could be exposed to concentrations greater than ERPG–2 and ERPG–3 if they are downwind. Because Gas Plant workers will be closest to the accident site, the plume will be dense and will probably be visible during the period of the greatest release. The workers could escape from the plume on foot provided they do not become immersed in the plume (in which case they would encounter very high chlorine concentrations). Workers attempting to fight the fire without an air supply could be overcome by chlorine gas. (Workers are directed not to fight fires but instead to call the fire department and evacuate the area.)

Under adverse dispersion conditions (light wind, stable plume), ERPG–2 concentrations are exceeded out to distances ranging from 2.6 to 2.7 miles (4.2 to 4.3 kilometers), while ERPG–3 concentrations are exceeded out to distances of 1.1 to 1.2 miles (1.8 to 1.9 kilometers). Under conservative daytime dispersion, ERPG–2 concentrations are exceeded out to distances ranging from 1.2 to 1.4 miles (1.9 to 2.3 kilometers), while ERPG–3 concentrations are exceeded to distances ranging from 0.57 to 0.66 mile (0.92 to 1.1 kilometer). Average numbers of people affected by these concentrations are shown in Table G.5.5.2–2, which summarizes the modeling results for CHEM–02. Note that this release occurs within the LANL boundary. The town of Los Alamos is separated from the release point by wide, deep canyons that would trap and steer the highest concentrations of the plume away from the town site. The average number of people exposed is governed by numerous directions of release where no or few members of the public are located. If, however, the plume blows toward the most heavily populated area of TA–3 (which occurs less than 10 percent of the time), the number of people exposed to concentrations greater than ERPG–2 and ERPG–3 could number in the many hundreds to low thousands.

G.5.5.3 *CHEM–03, Single Cylinder Chlorine Release from Gas Plant*

General Scenario Description

Like CHEM–02, CHEM–03 occurs at TA–3–476. However, CHEM–03 involves the release of chlorine from a single 150-pound cylinder. This scenario was evaluated in the Gas Plant Safety Assessment (LANL 1994b). Three contributors were identified: (1) release without fire due to an on-site transportation accident at the toxic gas storage shed (Scenario 5), frequency from 10^{-4} to 10^{-3} per year; (2) release due to drop of toxic gas cylinder (Scenario 11), frequency from 10^{-4} to 10^{-3} per year; and (3) release due to deterioration of cylinders from weather (Scenario 23), frequency from 10^{-4} to 10^{-3} per year. The properties of chlorine gas and heavy gases were addressed in section G.5.1.5.

CHEM–03 Release Mechanisms

As noted above, three release mechanisms were postulated in the Gas Plant SA (LANL 1994b). Release due to impact of a cylinder by a truck is discounted here because of the installation of bumpers in front of the toxic gas storage shed, which was accomplished as a corrective action after the SA was performed. Chlorine releases from a single cylinder due to a dropped cylinder and due to long-term exposure to weather are addressed separately below.

No Action Frequency Analysis

Because all cylinders are stored with their valve covers installed (Lovato and Nielsen 1997), the scenario would have to involve a second human error in failing to install the valve cover correctly at the supplier facility. A third error would also be required because receipt inspections are performed and the status of the valve cover would normally be checked at this time.

On the basis of these considerations, the frequency of this contributor can be calculated using the following equation:

$$F_{DROP} = N_{HANDLED} \text{ x } H_{DROP} \text{ x } H_{COVER} \text{ x } H_{CHK} \text{ x } C_{FAIL}$$

where:

F_{DROP} = Frequency of dropped cylinder resulting in chlorine release

$N_{HANDLED}$ = Number of cylinders handled per year

H_{DROP} = Human error, dropping cylinder during handling

H_{COVER} = Human error, failure to install valve cover properly

H_{CHK} = Human error, failing to check valve cover installation during receipt inspection

C_{FAIL} = Conditional probability of valve failure when cylinder is dropped

The number of cylinders handled annually under the No Action Alternative is 70 based on the information presented above in section G.5.5.1. Each cylinder is handled twice (once during placement into TA–3–476 for storage and again during retrieval from storage). Thus, the total number of handling events is 140.

We estimate the basic human error rate as 0.003 per demand. Although perhaps not directly applicable to DOE facilities, a study of human reliability with emphasis on nuclear power plant applications supports this number (Swain and Guttmann 1983). Considering that the personnel handling the cylinder expect the valve cover to be installed, no additional credit is taken here for extra precautions that might be observed if the workers believed that their life would be endangered by mistakes. No recovery probability is assessed because once the cylinder is dropped there is no opportunity to recover the situation. The human error probability (HEP) for failing to install the valve cover properly is 0.003 (failure to properly mate a connector; Swain and Guttmann 1983). Failure to check the valve cover installation during receipt inspection is 0.1 (Swain and Guttmann 1983). The conditional probability of valve failure given that the cylinder is dropped with an improperly installed valve cover is judged to be no more than 0.25 because the cylinder can be dropped on the top, the bottom, or either side, and only dropping the cylinder on the top is judged to be associated with valve failure.

On the basis of these considerations, the above equation can be quantified as follows:

$$F_{DROP} = N_{HANDLED} \text{ x } H_{DROP} \text{ x } H_{COVER} \text{ x } H_{CHK} \text{ x } C_{FAIL}$$

$$= 140 \text{ x } 0.003 \text{ x } 0.003 \text{ x } 0.1 \text{ x } 0.25$$

$$= 3.2 \text{ x } 10^{-5} \text{ per year}$$

The Gas Plant SA identified failure of a cylinder due to deterioration from weather. This failure mode is essentially a random cylinder failure, especially considering that the cylinders are designed to be exposed to weather but are stored inside the toxic gas storage shed until they are picked up for shipment to the potable water chlorinator stations.

The frequency of random cylinder failure can be assessed as follows:

$$F_{RANDOM} = R_{HOUR} \text{ x (8,760 hr/yr) x } N_{CYL}$$

where:

F_{RANDOM} = Frequency of random cylinder failure

R_{HOUR} = Random failure rate per hour of a pressurized cylinder

8,760 hr/yr = The number of hours in a year

N_{CYL} = The number of cylinders in storage

The random failure rate for a pressurized cylinder is 1 x 10^{-9} per hour (Mahn et al. 1995). The number of cylinders in storage is ten full cylinders at any one time (Lovato and Nielsen 1997). Thus, the above equation can be quantified as follows:

$$F_{RANDOM} = R_{HOUR} \text{ x (8,760 hr/yr) x } N_{CYL}$$

$$= (1 \text{ x } 10^{-9}\text{/hr) x (8,760 hr/yr) x } 10$$

$$= 8.8 \text{ x } 10^{-5} \text{ per year}$$

The combined frequency of occurrence of a single cylinder toxic gas release is obtained from the following equation:

$$F_{TOTAL} = F_{DROP} + F_{RANDOM}$$

$$= (3.2 \text{ x } 10^{-5}) + (8.8 \text{ x } 10^{-5})$$

$$= 1.2 \text{ x } 10^{-4} \text{ per year}$$

Expanded Operations Alternative Frequency Analysis

There is only one difference for the Expanded Operations Alternative that affects sequence frequency. In the Expanded Operations Alternative there are 79 cylinders handled per year, with a total of 158 handling events. The equation above for the cylinder drop scenario can be reevaluated for the Expanded Operations Alternative as follows:

$$F_{DROP} = N_{HANDLED} \times H_{DROP} \times H_{COVER} \times H_{CHK} \times C_{FAIL}$$

$$= 158 \times 0.003 \times 0.003 \times 0.1 \times 0.25$$

$$= 3.6 \times 10^{-5} \text{ per year}$$

Because the frequency of random failure does not change, the combined frequency of occurrence of a single cylinder toxic gas release for the Expanded Operations Alternative is obtained as follows:

$$F_{TOTAL} = F_{DROP} + F_{RANDOM}$$

$$= (3.6 \times 10^{-5}) + (8.8 \times 10^{-5})$$

$$= 1.2 \times 10^{-4} \text{ per year}$$

Reduced Operations Alternative Frequency Analysis

There is only one difference for the Reduced Operations Alternative that affects sequence frequency. Based on the analysis of scenario CHEM–02 (Rev. 0, 04/08/97), there are 66 cylinders handled per year, with a total of 132 handling events. The equation for cylinder drop can be reevaluated as follows:

$$F_{DROP} = N_{HANDLED} \times H_{DROP} \times H_{COVER} \times H_{CHK} \times C_{FAIL}$$

$$F_{DROP} = 132 \times 0.003 \times 0.003 \times 0.1 \times 0.25$$

$$F_{DROP} = 3.0 \times 10^{-5} \text{ per year}$$

Because the frequency of random failure does not change, the combined frequency of occurrence of a single cylinder toxic gas release for the Expanded Operations Alternative is obtained as follows:

$$F_{TOTAL} = F_{DROP} + F_{RANDOM}$$

$$= (3 \times 10^{-5}) + (8.8 \times 10^{-5})$$

$$= 1.2 \times 10^{-4} \text{ per year}$$

Greener Alternative Frequency Analysis

The number of cylinders handled per year under the Greener Alternative is the same as the No Action Alternative. Thus, the frequency of a release of a single cylinder of chlorine gas is the same, or a frequency of 1.2×10^{-4} per year.

Uncertainties and Sensitivities Affecting the Frequency of CHEM–03

Because the number of cylinders handled per year and the number of trips per year are relatively well known, the principal uncertainties in the frequency of a single cylinder release of chlorine relate to the error factors for the human errors modeled. These error factors range from three to five (Swain and Guttman 1983). Even if an error factor of five were considered, the contribution to frequency of CHEM–03 would be about evenly split between the low-frequency human error leading to valve failure and the random failure of a cylinder.

Source Term Calculations

The available material for release in the CHEM–03 source term is limited to the complete contents of one chlorine cylinder, or 150 pounds. However, the release through the valve orifice is such that 68 to 75 pounds of chlorine release quickly; but, in the process the cylinder is cooled below the boiling point of the chlorine liquid remaining in the cylinder and the release is essentially terminated. If no recovery actions are taken, the cylinder would ultimately heat up above the boiling temperature of chlorine and a release would resume, but at a very low rate, which is unlikely to result in any health consequences downwind of the cylinder.

Uncertainties and Sensitivities Affecting the Source Term for CHEM–03

EPA Risk Management Program off-site consequence analysis guidance issued in 1996 indicates that when a toxic gas is released inside a building that has direct contact with the outside environment (such as a shed), the release rate is ameliorated somewhat due to mixing within the shed. The guidance suggests multiplying the release rate by 0.55 (EPA 1996). The same quantity of gas is released, but the release duration is extended beyond what would be predicted by the ALOHA™ code. This reduction factor is not applied here because the release could also occur outdoors (human error dropping a cylinder).

Consequences of CHEM–03 for Facility Workers and the Public

Consequences of the CHEM–03 accident are reported separately for facility workers and the public. Gas Plant personnel who are directly involved in handling the cylinders of chlorine could quickly be exposed to high concentrations for the human error (cylinder dropping) contributor to the scenario frequency. In the case of the random cylinder failure contributor, however, it is more likely that no one will be near the toxic gas storage shed when the leakage begins. Other Gas Plant personnel located outdoors at the time of the accident could be exposed to concentrations greater than ERPG–2 and ERPG–3. However, these personnel would be in a position to evacuate the affected area very quickly (due to being outdoors), which would reduce the potential for serious health effects.

Under adverse dispersion conditions (stable atmosphere), the ERPG–2 distance ranges from 0.76 to 0.79 mile (1.2 to 1.3 kilometer), and the ERPG–3 distance ranges from 0.32 to 0.33 mile (0.52 to 0.53 kilometer). Under conservative daytime dispersion conditions, the ERPG–2 distance ranges from 0.62 to 0.71 miles, and the ERPG–3 distance ranges from 0.27 to 0.31 mile. The average number of people exposed under conservative daytime dispersion conditions is shown in Table G.5.5.3–1.

G.5.5.4 *CHEM–04, Single Container Release of Toxic Gas from Waste Gas Cylinder Storage*

General Scenario Description

TA–54–216 is located at TA–54 Area L, which provides permitted storage for hazardous waste and liquid- or volatile-organic-containing waste that is contaminated with both hazardous and radioactive components. The TA–54–216 storage canopy is used to store waste gas cylinders pending final determination of disposal options. The storage canopy is a fabric dome structure that is open on three sides (east, north, and west) to provide ventilation.

From 1983 to November 1996, TA–54–216 has received a total of 4,144 waste cylinders. Currently, approximately 200 cylinders are stored at the facility and are representative of what TA–54–216 is anticipated to have in inventory in the future. Occasionally, a large influx of gas cylinders may occur due to decontamination and decommissioning activities at LANL.

Activities at TA–54–216 are generally limited to the receipt, storage, staging, and shipment of gas cylinders. Gas cylinders are stored and moved in gas cylinder racks by forklift (gasoline or electric). At some time in the future, it will be necessary to repackage some of the gases into DOT-qualified packages so that they may be shipped off site for disposal. Facility activities generally do not involve the removal of cylinder valve covers (some do not have covers but the cylinder design protects the valve). The exception to this is when the valve covers are briefly removed for verification that the valves are secure and leak-tight prior to off-site shipment for disposal.

Based on the type of activities conducted at TA–54–216, potential accident initiators leading to an individual cylinder release include random failure of a cylinder, failure of a cylinder due to a forklift accident, or human error during cylinder handling.

This accident was not evaluated in LANL safety analysis documentation reviewed in the preparation of the SWEIS.

Properties of Selenium Hexafluoride Gas

Selenium hexafluoride is a colorless toxic gas (TWA is 0.05 parts per million) that irritates the skin and eyes; may cause severe pulmonary irritation with coughing, choking, and shortness of breath; and also may cause pulmonary edema. It is stable at normal temperatures but has hazardous decomposition products. There is no evidence of carcinogenicity.

No Action Alternative Frequency Analysis

The frequency of a single cylinder release of any gas was calculated at TA–54–216 using the inventory of gas cylinders at the facility and associated movements. This provides a bounding estimate of risk associated with a single cylinder release and gives a broader representation of risk for site-wide activities potentially leading to a single container release of a toxic gas (postulated chlorine releases are evaluated separately).

Human error contributions (dropping a cylinder during handling with valve cover removed or improperly installed) are considered negligible for off-site shipments. This is based on verification of valve leak tightness while the cylinder is in the cylinder rack (precluding a drop accident), the low probability of the valve cover being improperly reinstalled (this would be self evident), and the hazards training and awareness of involved personnel. The combined frequency (F_{TOTAL}) of a single cylinder release may be quantified as:

$$F_{TOTAL} = F_{RANDOM} + F_{FORKLIFT}$$

where:

F_{RANDOM} = Frequency of a toxic gas release due to a random cylinder failure

$F_{FORKLIFT}$ = Frequency of a toxic gas release due to a forklift accident

Random cylinder failure can occur due to a variety of causes (including cylinder defects, weathering, corrosive attack, damage to valving). For random failure, the frequency can be estimated as follows:

$$F_{RANDOM} = 8{,}760 \times R_{HOUR} \times N_{CYL}$$

where:

F_{RANDOM} = Frequency of a toxic gas release due to a random cylinder failure

8,760 = Number of hours in a year (24 hours x 365 days)

R_{HOUR} = Random failure rate of pressurized cylinder (10^{-9} per hour; Mahn et al.1995)

N_{CYL} = Number of toxic gas cylinders at risk (200 representative inventory)

Thus, the above equation can be quantified as follows:

$$F_{RANDOM} = 8{,}760 \times R_{HOUR} \times N_{CYL}$$

$$= 8{,}760 \text{ hr} \times (1 \times 10^{-9}/\text{hr}) \times 200$$

$$= 1.8 \times 10^{-3} \text{ per year}$$

The frequency of a forklift accident leading to a release of a toxic gas from a single cylinder may be analyzed using the following equation:

$$F_{FORKLIFT} = N_{FMOVE} \times C_{PFACC} \times C_{PCFAIL}$$

where:

$F_{FORKLIFT}$ = Frequency of a toxic gas release due to a forklift accident

N_{FMOVE} = Number of forklift movements per year

C_{PFACC} = Conditional probability of a forklift accident per movement

C_{PCFAIL} = Conditional probability of toxic gas cylinder failure per forklift accident

Between 1983 and November 1996, TA–54–216 received 4,144 toxic waste cylinders. Thus, annual throughput is approximated as 300 (4,144/14) toxic gas cylinders per year. Forklift movements at TA–54–216 occur at the time of receipt and for off-site shipment. Additionally, it is assumed that at least one forklift movement is made for inventory control/staging while stored at TA–54–216. Multiple cylinders are stored in racks. It is conservatively assumed that only two cylinders are stored per rack, resulting in an estimated 450 (3 x 300/2) forklift movements per year. The conditional probability of a forklift accident is estimated as 1 x 10^{-5} per forklift movement (LANL 1995g). Not all forklift accidents will be of sufficient severity to result in damage to a cylinder and a release of its contents. The conditional probability depends on the nature of the accident and how the individual cylinder is mechanically impacted by drop, puncture, and crush forces. There is a potential that any forklift accident at TA–54–216 would be aggravated by the uneven grade at the facility. There is an elevation grade transition of approximately 3.3 feet (1 meter) that runs through the center length of the canopy. To account for the foregoing, and because some of the cylinders are not U.S. Department of Transportation (DOT) certified, it is conservatively assumed that the conditional probability of a single cylinder failure per forklift accident is 0.5. Forklift accidents also may also involve multiple cylinder failures, such as a forklift fuel tank fire. This component of risk is quantified in accident Scenario CHEM–05.

Thus, the above equation can be quantified as follows:

$$F_{FORKLIFT} = N_{FMOVE} \times C_{PFACC} \times C_{PCFAIL}$$

$$= 450 \text{ moves} \times (1 \times 10^{-5} \text{ per move}) \times 0.5$$

$$= 2.3 \times 10^{-3} \text{ per year}$$

From the above analyses, the combined frequency of occurrence for a single cylinder release of toxic gas is estimated as:

$$F_{TOTAL} = F_{RANDOM} + F_{FORKLIFT}$$

$$= (1.8 \times 10^{-3}) + (2.3 \times 10^{-3})$$

$$= 4.1 \times 10^{-3} \text{ per year}$$

Expanded Operations Alternative, Reduced Operations Alternative, and Greener Alternative Frequency Analysis

There are no differences in operations or throughput across the alternatives for this scenario. Accordingly, the No Action Alternative frequency value represents all alternatives.

Uncertainties and Sensitivities Affecting the Frequency of CHEM–04

Several uncertainties are associated with the selected accident scenario frequency and conditional probability parameters. In all cases, realistically conservative values have been used based on identified accident conditions and facility-specific conditions.

Source Term Calculations

Accident screening of the historical chemical inventory data identified selenium hexafluoride as the dominant chemical-of-concern for a single toxic gas cylinder (75 liters) release. This chemical had the greatest ERPG–2 and ERPG–3 distances for a single cylinder out of the historical inventory, which should be broadly representative of future activities. In fact, it should be generally the case that future gas cylinders passing through TA–54–216 would be less hazardous than in the past, due to effort by LANL to reduce its inventory of hazardous chemicals.

The release is modeled as a direct release of 7.5 liters of gas per minute for 10 minutes. The release is modeled in this manner because there is insufficient information available regarding cylinder size and pressure to perform a more precise calculation. There is no variation in the MAR or postulated accident conditions from the No Action Alternative across the remaining alternatives.

Uncertainties and Sensitivities Affecting the Source Term for CHEM–04

The source term calculation is based on the single cylinder's size and chemical producing the largest ERPG–2 and ERPG–3 distances for the toxic gas cylinders processed through TA–54–216 in the historical database. Given this, unless circumstances change significantly (i.e., a much more toxic chemical is handled in significant quantity), this release should be bounding. It should be noted that it is conservative to assume that the cylinder is full; it is likely that the inventory may have been partially or largely depleted during use.

Consequences of CHEM–04 for Facility Workers and the Public

Typically four to five people actively work in the Area L yard in which TA–54–216 is located. An additional ten people may be present in the yard in support of construction activities. Depending on the nature of activity at TA–54–216, zero to three people would be expected to be present at the facility itself.

Traumatic injuries or fatalities could occur from missiles for any individuals present at the time of cylinder rupture or involved in the forklift accident. Health consequences from the toxic nature of the released gas also may occur. Depending on exposure levels and durations, four possible adverse health outcomes may result: (1) mild, transient adverse health effects; (2) reversible, but more serious adverse health effects; (3) irreversible, adverse health effects; and (4) life-threatening health effects.

For outdoor incidents, facility workers are trained (Emergency Action Plan) to stop all activity and to leave the immediate area for any release of an unknown substance or known hazardous substance. Personnel are trained to alert others and to activate applicable alarms on the way out and to proceed upwind (based on direction of visible windsock, wind vane, or other indicators) to the nearest muster station. If not at immediate risk, the worker is trained to shutdown equipment. Emergency response planning also includes provisions for evacuation. These actions will serve to mitigate impacts to workers.

Under adverse dispersion conditions, the ERPG–2 distance is about 230 yards (210 meters). Under conservative daytime dispersion conditions, the ERPG–3 and ERPG–2 exposure distances are less than 100 yards. The average number of people exposed to greater than ERPG–3 and ERPG–2 concentrations for conservative daytime dispersion is provided in Table G.5.5.4–1.

G.5.5.5 *CHEM–05, Multiple Cylinder Release of Toxic Gas from Waste Gas Cylinder Storage at TA–54–216*

General Scenario Description

This scenario occurs at the same facility as CHEM–04; however, it differs in that the consequence results from the bounding historical inventory of chemicals present in multiple cylinders. Accident screening of the historical chemical inventory data identified sulfur dioxide as the dominant chemical-of-concern for a multiple toxic gas cylinder release.

Properties of Sulfur Dioxide Gas

Sulfur dioxide is a colorless, nonflammable gas (or liquid under pressure). Sulfur dioxide (SO_2) is listed on EPA's Extremely Hazardous Substances List. It is a poisonous gas chiefly affecting the upper respiratory tract and the bronchi, and it is also a corrosive irritant to the eyes, skin, and mucous membranes (Lewis 1993).

CHEM–05 Release Mechanisms

Based on the type of activities conducted at TA–54–216, potential accident initiators leading to a multiple cylinder release include propagation of a random failure of a cylinder (rupture) from missiles, a forklift fire or a delivery/shipment truck fire incident, or rupture and subsequent BLEVE (boiling liquid expanding vapor explosion) of the adjacent propane tank. The resulting fireball and thermal radiation would be the primary concern associated with potential to impact multiple cylinders. Propane tank leak explosion hazards include the potential for significant overpressure and missiles.

No Action Alternative Frequency Analysis

While sulfur dioxide is the dominant chemical-of-concern for a multiple cylinder release, the frequency of a multiple cylinder release of any gas was calculated at TA–54–216 using the typical inventory of gas cylinders at the facility and associated movements. This provides a bounding estimate of risk associated with a multiple cylinder release of sulfur dioxide and gives a broader representation of risk for site-wide activities potentially leading to a multiple cylinder release of a toxic gas (postulated chlorine releases are evaluated separately).

Potential accident initiators leading to a multiple cylinder release include propagation of a random failure of a cylinder (rupture) from missiles, a forklift fire or a delivery/shipment truck fire incident, or rupture and subsequent BLEVE/explosion of the adjacent propane tank. Thus, the combined frequency (F_{TOTAL}) of a multiple cylinder release may be quantified as:

$$F_{TOTAL} = F_{RANDOM} + F_{FLFTFIRE} + F_{TRKFIRE} + F_{PROTANK}$$

where:

F_{RANDOM} = Frequency of a toxic gas release due to a random cylinder failure

$F_{FLFTFIRE}$ = Frequency of a toxic gas release due to a forklift fire

$F_{TRKFIRE}$ = Frequency of a toxic gas release due to a truck fire

$F_{PROTANK}$ = Frequency of a toxic gas release due to detonation of the propane tank

Random failure can occur due to a variety of causes (including cylinder defects, weathering, corrosive attack, damage to valving). For propagation of a random failure resulting in a multiple cylinder release, the frequency (F_{RANDOM}) can be estimated as follows:

$$F_{RANDOM} = 8{,}760 \times R_{HOUR} \times N_{CYL} \times C_{PROP}$$

where:

8,760 = Number of hours in a year (24 hours x 365 days)

R_{HOUR} = Random failure rate of pressurized cylinder (1 x 10^{-9}/hr) (Mahn et al.1995)

N_{CYL} = Number of toxic gas cylinders at risk (200 representative inventory)

C_{PROP} = Conditional probability of propagating failure given one cylinder ruptures

The CMR Building SAR (LANL 1995c) indicates based on historical experience that a leak is 20 times more likely to occur than a rupture. Leaks will not propagate unless the leaked gas is flammable or pyrophoric; sulfur dioxide is neither. Consequently, conservatively assuming that propagation occurs given a rupture, the conditional probability of propagation is 0.05 (1/20). This value is considered to be very conservative, especially considering the separation of several of the cylinder racks to accommodate forklift movements. The above equation can be quantified as follows:

$$F_{RANDOM} = 8{,}760 \times R_{HOUR} \times N_{CYL} \times C_{PROP}$$

$$= 8{,}760 \times (1 \times 10^{-9}) \times 200 \times 0.05$$

$$= 8.8 \times 10^{-5} \text{ per year}$$

The frequency of a forklift fire ($F_{FLFTFIRE}$) leading to a release of toxic gas from multiple cylinders may be analyzed using the following equation:

$$F_{FLFTFIRE} = N_{FMOVE} \times N_{HOUR} \times F_{FUEL} \times C_{PING}$$

where:

N_{FMOVE} = Number of forklift movements per year

N_{HOUR} = Number of hours per forklift movement

F_{FUEL} = Frequency of a fuel tank rupture per hour

C_{PING} = Conditional probability of ignition given a fuel tank rupture and subsequent propagation of failure

From 1983 to November 1996, TA–54–216 received 4,144 waste cylinders. Thus, annual throughput has been approximately 300 (4,144/14) cylinders per year. Forklift movements at TA–54–216 occur at the time of receipt and for off-site shipment. Additionally, it is assumed that at least one forklift movement is made for inventory control/staging while stored at TA–54–216. Multiple cylinders are stored in racks. It is conservatively assumed that only two cylinders are stored per rack, resulting in an estimated 450 (3 x 300/2) forklift movements per year. It is conservatively assumed that each forklift movement has a duration of 0.5 hour.

The frequency of a forklift fuel tank rupture and a resulting fire is assessed for TA–54–214 based on methods and data contained in the TA–54, Area G hazard analysis (LANL 1995g) and the evaluation of ignition probabilities given a tank rupture by the Reliability Analysis Center in Rome, New York (RAC 1991). The frequency of a fuel tank rupture was assessed as 2.3×10^{-5} per hour in the TA–54 hazard analysis (LANL 1995g). For a nondiesel fuel (propane), the conditional probability of ignition given a rupture is assigned a value of 1×10^{-2}.

Thus, the above equation can be quantified as follows:

$$F_{FLFTFIRE} = N_{FMOVE} \times N_{HOUR} \times F_{FUEL} \times C_{PING}$$

$$= 450 \times 0.5 \times (2.3 \times 10^{-5}) \times 0.01$$

$$= 5.2 \times 10^{-5} \text{ per year}$$

The frequency of a truck fuel leak and fire contributor accident can be estimated using the following equation:

$$F_{FIRE} = N_{SHIPMENTS} \times C_{LEAK} \times C_{PFIRE}$$

where:

F_{FIRE} = Frequency of a fire at TA–54–216

$N_{SHIPMENTS}$ = Number of shipments to or from TA–54–216 per year

C_{LEAK} = Conditional probability of fuel leak per shipment

C_{PFIRE} = Conditional probability of a fire given a fuel leak and subsequent propagation of failure

The frequency of a fuel system leak or fuel tank leak and a resulting fire is assessed for TA–54–216 based on methods and data contained in the TA–54, Area G Hazard Analysis (LANL 1995g) and the evaluation of TRU waste transportation by H&R Technical Associates, discussed in section G.5.5.1. On a per trip basis, the likelihood of a fuel leak is 0.1/78, or 1.3 x 10^{-3} per trip. The conditional probability of a fire given a fuel leak is 4.7 x 10^{-3} per fuel leak. The number of shipments is estimated at 60 shipments per year (300 cylinder throughput per year x 2 shipments per cylinder/ 10 cylinders per shipment). Thus, the above equation can be quantified as follows:

$$F_{FIRE} = N_{SHIPMENTS} \times C_{LEAK} \times C_{PFIRE}$$

$$= 60 \times (1.3 \times 10^{-3}) \times (4.7 \times 10^{-3})$$

$$= 3.7 \times 10^{-4} \text{ per year}$$

For a random tank failure and subsequent BLEVE/explosion (F_{RANDOM}), the frequency can be estimated as follows:

$$F_{RANDOM} = 8{,}760 \times R_{HOUR} \times C_{PEXP}$$

where:

8,760 = Number of hours in a year (24 hours x 365 days)

R_{HOUR} = Random tank failure rate per hour

C_{PEXP} = Conditional probability of a BLEVE/ explosion and subsequent propagation of failure

The random failure rate of a pressurized tank, accounting for in-service inspections is 10^{-10} per hour (Mahn et al. 1995). The conditional probability of a BLEVE/explosion versus no ignition or jet flaming is conservatively estimated to be 0.25 on the basis that propane has a very narrow explosive range (lower explosive limit of 2.1 and an upper explosive limit of 9.5) (MGP 1997).

Thus, the above equation can be quantified as follows:

$$F_{RANDOM} = 8{,}760 \times R_{HOUR} \times C_{PEXP}$$

$$= 8{,}760 \times (1 \times 10^{-10}) \times 0.25$$

$$= 2.2 \times 10^{-7} \text{ per year}$$

From the above analyses, the combined frequency of occurrence for a multiple cylinder release of toxic gas is estimated as:

$$F_{TOTAL} = F_{RANDOM} + F_{FLFTFIRE} + F_{TRKFIRE} + F_{PROTANK}$$

$$F_{TOTAL} = (8.8 \times 10^{-5}) + (5.2 \times 10^{-5}) + (3.7 \times 10^{-4}) + (2.2 \times 10^{-7})$$

$$F_{TOTAL} = 5.1 \times 10^{-4} \text{ per year}$$

Expanded Operations Alternative, Reduced Operations Alternative, and Greener Alternative Frequency Analysis

No differences in operations across the alternatives have been identified for this accident scenario. Accordingly, the above frequency calculations represent all alternatives.

Uncertainties and Sensitivities Affecting the Frequency of CHEM–05

Several uncertainties are associated with the selected accident scenario frequency and conditional probability parameters. In all cases, realistically conservative values have been used based on identified accident conditions and facility specifics.

Source Term Calculations

The source term for this accident scenario is based on a release of the contents of multiple toxic gas cylinders. Accident screening of the current chemical inventory data identified sulfur dioxide as the dominant chemical-of-concern for a multiple toxic gas cylinder (136 liters) release. The release is modeled as two, 150-pound cylinders releasing 30 pounds per minute for 10 minutes. The release is modeled as a continuous release because insufficient information is available concerning the cylinder size and pressure.

Uncertainties and Sensitivities Affecting the Source Term for CHEM–05

Sulfur dioxide is the dominant chemical-of-concern from a toxic standpoint. Source term uncertainties include the total number of cylinders that may be affected by a specific accident initiator, the release rate from the cylinders, and the possible influences of building wakes and buoyancy considerations for fire events.

Consequences of CHEM–05 for Facility Workers and the Public

Typically four to five operations personnel actively work in the Area L yard where TA–54–216 is located. An additional ten people may be present in the yard in support of construction activities. Depending on the nature of activity at TA–54–216, zero to three people would be expected to be present at the facility itself.

Traumatic injuries or fatalities could occur from missiles for any individuals present at the time of the postulated cylinder ruptures or involved in the forklift/truck fire incidents. Health consequences from the toxic nature of the released gas also may occur. Depending on the exposure levels and durations, four possible adverse health outcomes may result: (1) mild, transient adverse health effects; (2) reversible but more serious adverse health effects; (3) irreversible, adverse health effects; and (4) life-threatening health effects.

For outdoor incidents, facility workers are trained (Emergency Action Plan) to stop all activity and to leave the immediate area for any release of an unknown substance or known hazardous substance. Personnel are trained to alert others and to actuate applicable alarms on the way out and to proceed upwind (based on direction of visible windsock, wind vane, or other indicators) to the nearest muster station. If not at immediate risk, the worker is trained to shutdown equipment. Emergency response planning also includes provisions for evacuation. These actions will serve to mitigate impacts to the workers.

Under adverse dispersion conditions (stable atmosphere), the ERPG–2 distance is 1.7 miles (2.7 kilometers), while the ERPG–3 distance is 0.75 mile (1.2 kilometer). Under conservative daytime dispersion conditions, the ERPG–2 distance ranges from 0.62 to 0.81 mile (1.0 to 1.3 kilometers), while the ERPG–3 distance ranges from 0.28 to 0.34 mile (0.45 to 0.55 kilometer). The average affected population at higher than ERPG–2 and ERPG–3 concentrations under conservative daytime dispersion conditions is shown in Table G.5.5.5–1. There are only two directions (west and northwest) where the off-site population can be exposed, due to the remoteness of the site.

G.5.5.6 *CHEM–06, Chlorine Gas Release from Outside the Plutonium Facility*

General Scenario Description

TA–55–4 is the LANL Plutonium Facility. At TA–55–4, gaseous chlorine is used for various processes. The chlorine is supplied by piping from a 150-pound cylinder that is kept in a storage room for corrosive and toxic gases, outside TA–55–4. When the chlorine is not in use, the piping is shut off at the chlorine tank valve, and the line is purged and then pressurized with argon to prevent leaks during off-duty hours (LANL 1996k).

In this scenario, a chlorine release occurs due to a failure of piping associated with a chlorine gas cylinder. The piping failure is assumed to occur outside TA–55–4, leading to a release directly to the atmosphere (LANL 1996k). Chlorine is a heavy gas, which will affect the downwind dispersion of the gas following release. The properties of chlorine gas and heavy gases are discussed in section G.5.5.1.

Accident Scenario CHEM–06 was analyzed in detail in the TA–55–4 SAR. The SAR analysis considered significant inventories of hazardous chemicals with potential for release affecting workers and the off-site population. The hazard analysis that underlies the SAR identified a spill of nitric acid, a spill of hydrochloric acid, a release of gaseous fluorine or hydrogen fluoride, and a release of gaseous chlorine as possible scenarios (LANL 1996k).

The SAR evaluated the tests through which DOT-approved storage cylinders are placed, and concluded that catastrophic failures of gas bottles are not expected. Rather, the SAR found that chronic releases from improper or failed connectors at piping manifolds are the most likely cause of a release. Using a Gaussian dispersion model, the SAR analyzed the consequences of the bounding toxic gas releases at a 2,952-foot (900-meter) distance where public exposure is possible. Chlorine was found to produce the bounding consequence (LANL 1996k).

The SAR analysis assumed a release of 150 pounds of chlorine gas over a 15-minute period at a release height of 16 feet (5 meters). The downwind concentration of chlorine was calculated using the CHEM-MIDAS heavy gas dispersion model, and evaluated for adverse dispersion conditions (in this case, stability Class F and 1.9 meters per second wind speed). The code calculated a concentration at the Royal Crest Trailer Court of 8 parts per million (LANL 1996k). The ERPG–3 concentration for chlorine is 20 parts per million, while the ERPG–2 level is 3 parts per million.

CHEM–06 Release Mechanisms

The TA–55 SAR assumed the chlorine release was due to a break in the line outside TA–55–4.

No Action Alternative Frequency Analysis

During the facility walkdown, it was learned that the TA–55 SAR frequency bin assignment of 10^{-2} to 10^{-1} per year for this scenario was based on one event in 16 years (1978 to1996) in which a cylinder of chlorine was partially released as a result of mechanical damage to the gas line. Because this was a partial failure, the calculation of frequency based on one event in 16 years (6.3×10^{-2} per year) is conservative.

Expanded Operations Alternative, Reduced Operations Alternative, and Greener Alternative Frequency Analysis

There are no differences in operations across the alternatives affecting the chlorine system. The frequency estimated above for the No Action Alternative is considered to be applicable to the remaining alternatives.

Uncertainties and Sensitivities Affecting the Frequency of CHEM–06

The TA–55 hazard analysis places the rupture of the gas manifold due to impact by heavy equipment in the frequency bin from 10^{-4} to 10^{-2} per year (LANL 1996l). The hazard analysis also identifies a gas leak in Room 116 in the same frequency bin, citing Unusual Occurrence Report 89832 (LANL 1996l). Figure 2A–3 of the TA–55 SAR identifies Room 116 of TA–55–4 as a corridor between the 100 Area and 200 Area rooms on the first floor of the building. This release would affect TA–55–4 workers in the first instance, but would ultimately be released to the environment.

Other failure modes for chlorine release are possible, such as random cylinder or manifold failure, or human error during cylinder changeout (see section G.5.5.1). Given the much lower level of activity at TA–55–4 for chlorine cylinder changeout, the experience-based frequency cited above is selected.

Source Term Calculations

The release is assumed to be a ground level release of a full, 150-pound cylinder. There are no differences in source term across the SWEIS alternatives. The release is modeled as a 15-pound per minute release into the building for 10 minutes, in accordance with the description of the release in the TA–55 SAR.

The EPA RMP off-site consequence analysis guidance issued in 1996 indicates that when a toxic gas is released inside a building that has direct contact with the outside environment (such as a shed), the release rate is ameliorated somewhat due to mixing within the shed. The guidance suggests multiplying the release rate by 0.55 (EPA 1996). In order to obtain the release duration, it is then necessary to divide the total quantity released by the effective release rate. When this method is applied to the TA–55 chlorine gas leak, the release duration is increased to 18.2 minutes and the outdoor concentrations proportionately reduced.

Uncertainties and Sensitivities Affecting the Source Term for CHEM–06

The release rate from the cylinder itself is modeled as a continuous rate; whereas, releases from cylinders vary with time. The 10-minute period is regarded as conservative. The factor of 0.55 accounting for the retention time prior to release to the outdoors is uncertain for this storage shed.

Consequences of CHEM–06 for Facility Workers and the Public

Facility worker and public consequences are addressed separately. Because the air intakes for TA–55–4 are on the west end of the building at a point centered 18 feet (5.5 meters) above the ground, and the chlorine release point is on the north side of the building (LANL 1996k), it is unlikely that chlorine released into the air would be drawn into the building by the ventilation system. Moreover, there is a 30-inch (76-centimeter) diameter butterfly valve in the intake ductwork that can be closed manually to act as a shut-off valve (LANL 1996k). TA–55 personnel located outdoors at the time of the accident could be exposed to high concentrations of chlorine. However, these personnel would be in a position to evacuate from the affected area very quickly (being outdoors), which should reduce the potential for health effects.

Under adverse dispersion conditions (stable atmosphere), the ERPG–2 distance ranges from 0.58 to 0.66 mile (0.93 to 1.1 kilometer), while the ERPG–3 distance is 0.2 mile (0.32 kilometer). Under conservative daytime dispersion conditions, the ERPG–2 distance is about 0.27 mile (0.43 kilometer), while the ERPG–3 distance is about 0.10 mile (0.16 kilometer). The average number of members of the public exposed above ERPG–2 and ERPG–3 concentrations under conservative daytime dispersion conditions is shown in Table G.5.5.6–1.

TABLE G.5.5.6–1.—*Summary Results for Scenario CHEM–06*

ALTERNATIVE	ACCIDENT FREQUENCY	SOURCE TERM AND CONSEQUENCES
No Action	6.3×10^{-2}	150 pounds of chlorine released in 18.2 minutes; average number of people exposed above ERPG–2 and ERPG–3 concentrations is 102 and 7, under conservative daytime dispersion conditions.
Expanded Operations	6.3×10^{-2}	Same as No Action Alternative.
Reduced Operations	6.3×10^{-2}	Same as No Action Alternative.
Greener	6.3×10^{-2}	Same as No Action Alternative.

G.5.6 Radiological Accidents

G.5.6.1 *RAD–01, TRU Waste Container Storage Area Fire at NDA/NDE Facility (TA–54–38)*

General Scenario Description

The Nondestructive Assay/Nondestructive Examination (NDA/NDE) Facility conducts verification assay and radiographic examination of unopened waste containers to confirm compliance with waste acceptance criteria (WAC). An outdoor container storage area (40 feet by 40 feet [12 meters by 12 meters]) is designated to stage waste processed through the facility. The outdoor Container Storage Area has a RCRA Part B permitted capacity of 7,920 gallons of mixed waste, which is equivalent to 144, 55-gallon drums. However, the capacity of the Container Storage Area is administratively controlled to 23 DOT Type A drums (of the type used for TRU waste). Scenario RAD–01 involves an airborne release of radioactive material due to a fire that develops at the outdoor Container Storage Area.

Properties of TRU Waste. Transuranic waste contains at least 100 nanocuries per gram of transuranium isotopes (primarily plutonium and americium). It is present in a wide variety of forms at LANL, some of which are combustible (e.g., paper, plastic, etc.) and some of which are not combustible (e.g., concrete).

RAD–01 Release Mechanisms. Potential accident initiators include: (1) truck fires, (2) forklift fires, (3) external fires (wild fires), (4) lightning strikes, and (5) aircraft accidents. Aircraft crash was evaluated in section G.4 and is not considered further here. Lightning may strike the Container Storage Area or pose an indirect hazard by initiating a wildfire. The Container Storage Area does not have lightning protection; however, a lightning strike would, at most, pose a localized hazard due to ignition of combustible waste. It would have a very limited opportunity to propagate with waste contained in metal drums and the low combustible loading of the storage array. Wild fires, initiated by lightning strikes or otherwise, do not pose a significant hazard considering the developed nature of the area (e.g., pavement) and the time available to take mitigative actions. A forklift fire would be credible but would be significantly bounded by the MAR for a truck fire accident.

Two truck fire scenarios could occur. The first is an accident involving a truck that causes a fuel leak and subsequent fire involving the Container Storage Area. This is judged not to be credible considering the low truck speeds involved in the confined yard area and the limited vehicle traffic, with the exception of forklift activity. The second involves a truck parked near the Container Storage Area that could experience a fuel system leak or fuel tank leak due to causes unrelated to a vehicle accident. Once a fuel leak occurs, ignition of the spilled fuel would lead to a fire that, if it is close enough to the Container Storage Area and if it is not suppressed, would envelop multiple waste containers. This scenario is retained for analysis. The TA–54–38 safety assessment did not evaluate the potential for a Container Storage Area fire (LANL 1996j).

No Action Alternative Frequency Analysis

The frequency of a truck fuel leak and subsequent fire accident can be estimated using the following equation:

$$F_{FIRE} = N_{SHIPMENTS} \times C_{LEAK} \times C_{PFIRE}$$

where:

F_{FIRE} = Frequency of truck fuel leak and fire

$N_{SHIPMENTS}$ = Number of shipments to or from the outdoor Container Storage Area at TA–54–38 per year

C_{LEAK} = Conditional probability of fuel leak per shipment

C_{PFIRE} = Conditional probability of a fire given a fuel leak

The frequency of a fuel system leak or fuel tank leak and a resulting fire is assessed for the outdoor Container Storage Area based on methods and data contained in the TA–54, Area G Hazard Analysis (LANL 1995g) and the evaluation of TRU waste transportation by H&R Technical Associates (Rhyne 1994). As described in section G.5.5, on a per trip basis, the likelihood of a fuel leak is 0.1/78, or 1.3 x 10^{-3} per trip. Similarly, as described in section G.5.5, the conditional probability of a fire given a fuel leak is 4.7 x 10^{-3} per fuel leak.

Facility truck movements may be associated with the loading dock, the truck bay (primarily in support of Waste Isolation Pilot Plant [WIPP] shipments), and the outdoor Container Storage Area. LANL intra-site shipments of TRU waste average approximately 16 drums per shipment, with a maximum of 40 drums. Because the Container Storage Area capacity is administratively controlled to a limit of 23 drums, it will be assumed that all shipments are 23-drum shipments. It is assumed that shipments associated with the outdoor Container Storage Area would primarily be conducted to receive waste from TA–54 Area G for staging just prior to shipment to WIPP and are insensitive to the facility throughput for assay verification. Each WIPP shipment consists of three Transuranic Packaging Transporter (TRUPACT)-IIs, each with a cargo capacity of 14 drums, for a total of 42 drums per WIPP shipment. Under the proposed action for WIPP, a total of 5,009 shipments to WIPP are projected over 35 years (DOE 1996d). This gives an average WIPP shipment rate of 143 per year. Thus, it is estimated that there are 261 (143 x 42/23) shipments per year from TA–54 Area G to the outdoor Container Storage Area.

Thus, the above equation can be quantified as follows:

$$F_{FIRE} = N_{SHIPMENTS} \times C_{LEAK} \times C_{PFIRE}$$

$$F_{FIRE} = 261 \times (1.3 \times 10^{-3}) \times (4.7 \times 10^{-3})$$

$$F_{FIRE} = 1.6 \times 10^{-3} \text{ per year}$$

Expanded Operations, Reduced Operations, and Greener Alternatives Frequency Analysis

Because the above frequency analysis is based on an average WIPP shipment schedule that is unaffected by the SWEIS alternatives, the frequency calculated above is considered to be applicable to all alternatives.

Uncertainties and Sensitivities Affecting the Frequency of RAD–01

Uncertainties in the frequency point estimates include the frequency of a fuel leak per shipment, the conditional probability of a fuel fire given a fuel leak, and the number of shipments per year.

Source Term Calculations

The MAR for the postulated accident is limited by the fraction of waste inventory immediately involved in the truck fuel pool fire. The MAR is estimated based on a 100-gallon (379-liter) fuel spill, yielding a burn area of 500 square feet (46 square meters). This is based on a burn area relationship of 250 square feet (23 square meters) for 50 gallons of fuel (RFETS 1994). Even allowing for aisle spacing as required by the *Resource Conservation and Recovery Act* (RCRA), the entire Container Storage Area inventory of 23 drums could be consumed in a fire of 500 square feet (46 square meters).

Potential waste forms present include solidified liquids (aggregate); surface contaminated, packaged combustible solids; and surface contaminated, noncombustible solids. The bounding ARF and RF products for these three waste forms in a thermal stress environment (fire) are 6 x 10^{-5}, 5 x 10^{-4}, and 6 x 10^{-5}, respectively (DOE 1994a). (Recall, ARF = airborne release fraction [the fraction of the material suspended in the air as an aerosol and thus available for transport due to the physical stresses from a specific accident of due to operation of HVAC systems], and RF = respirable fraction [the fraction of the aerosols that can be transported through the air and inhaled into the human respiratory system, commonly assumed to include particles of 10 microns aerodynamic equivalent diameter or less].)

Consequently, it can be concluded that releases will be dominated by combustible waste and the analysis will be limited to this waste form. It is conservatively assumed that 35 percent of the radiological inventory is present in combustible waste forms (combustible waste comprises approximately 10.3 percent of TRU waste by volume) (LANL 1996o, estimated from Table 4–1); however, the higher value is meant to account for the presence of decontamination trash, HEPA filters, and the relatively high surface contamination area to volume ratio for combustible materials. Separate calculations are performed for combustible and noncombustible forms. Thus, for the MAR (23 drums), the damage ratio is set equal to 0.35 for combustible material and at 0.65 for noncombustible forms. The Container Storage Area is located outdoors; consequently, the LPF is 1.0.

Currently, the average TRU radioactive material content per waste container is 8.9 plutonium-239 equivalent curies (PE-Ci) (LANL 1995f). Less than 1 percent of all TRU waste containers in the existing Area G inventory exceed 75 PE-Ci in radioactive material content (LANL 1995c). The predominant TRU waste generated at LANL is weapons-grade plutonium. The LANL fissile gram equivalent limit for this material type is 25 PE-Ci per drum (LANL 1995c). Revision 5 of the WIPP WAC limits the maximum plutonium-239 equivalent activity for untreated contact-handled TRU waste to be received by the facility to 80 PE-Ci per drum (if not overpacked). Considering that the postulated accident scenario involves multiple drums (23); that the drums represent a small fraction of the total TRU waste inventory managed at LANL, and their radioactive content could be skewed to the high end (depending on the waste generator source); and the above TRU limits; it is conservatively assumed that one drum contains the WIPP WAC limit for untreated waste of 80 PE-Ci (if not overpacked) and the other 22 drums involved in the fire have an average TRU content of 25 PE-Ci.

With the above information, the initial source term equation can be quantified as follows:

Initial Combustible Source Term = MAR x DR x ARF x RF x LPF

= [(22 x 25 PE-Ci) + (80 PE-Ci)] x 0.35 x (5 x 10^{-4}) x 1 x 1

= 0.11 PE-Ci

Initial Noncombustible Source Term = MAR x DR x ARF x RF x LPF

= [(22 x 25 PE-Ci) + (80 PE-Ci)] x 0.65 x (6 x 10^{-5}) x 1 x 1

= 0.02 PE-Ci

Total Initial Source Term = Initial Combustible + Initial Noncombustible

= 0.11 PE-Ci + 0.02 PE-Ci

= 0.13 PE-Ci

The MAR equals the initial MAR, minus the initial source term. The DR and LPF are set to 1. The ARR and RF are assigned values of 4 x 10^{-5} and 1.0, respectively, based on bounding resuspension factors for surface contaminated combustible solids exposed to ambient conditions (DOE 1994a). Thus, the suspension source term can be quantified as:

Suspension Source Term = MAR x DR x ARR x 24 hrs x RF x LPF

= (630 - 0.13 PE-Ci) x 1 x (4 x 10^{-5}) x 24 hrs x 1 x 1

= 0.60 PE-Ci

The suspension source term is conservative, considering that fire protection actions (e.g., foam, water spray) and contamination control measures would likely limit airborne releases significantly. This would reduce the suspension period from the 24 hours assumed above to a much smaller number, which could in principle be zero. The 24-hour calculation is retained as a conservative measure for impact estimation. There are no variations in source terms across the alternatives.

Uncertainties and Sensitivities Affecting the Source Term for RAD–01

A significant uncertainty for this postulated accident is quantification of the MAR in terms of the number of drums involved in the fire and their associated radioactive material content. Accepted methodologies and reasonably conservative radiological estimates have been made to provide an upper estimate of the source term.

It could be postulated that the truck fire would lead to an explosion of the truck's fuel. This accident would have a lower frequency, perhaps being incredible, but would not involve more than the 23 drums. The explosion could disperse the drums, perhaps beyond the range of the fire, but the release and airborne fraction would likely not increase. Section 5.1 of DOE Handbook 3010 (DOE 1994d) gives a median ARF of 8 x 10^{-5} and a bounding ARF of 5 x 10^{-4} for thermal stress on packaged combustible solids. The ARF used in this analysis was also 5 x 10^{-4}.

Consequences of RAD–01 for Facility Workers and the Public

Consequences for facility workers and the public are considered separately. On a day shift, a total of 12 facility workers (including truck bay activities) would typically be involved with facility operations and would be at risk for exposure to airborne radioactive material.

No acute fatalities are predicted to result from the postulated accident. The mean collective population dose is projected to total 72 person-rem (TEDE), resulting in 0.036 excess LCFs. Mean projected doses for MEIs (and their associated locations) and ground contamination levels are presented in Tables G.5.6.1–2 and G.5.6.1–3, respectively. Table G.5.6.1–1 summarizes the modeling results for RAD–01.

G.5.6.2 *RAD–02, Natural Gas Pipeline Failure, Ingestion, and Explosion/Fire at CMR*

General Scenario Description

This accident scenario involves the rupture of a 3-inch (8-centimeter) natural gas pipeline near the CMR Building (TA–3–29), no immediate ignition of the gas, transport of the gas to the CMR intake structure, and subsequent explosion and fire in Wing 7 of the CMR Building. Rupture of the natural gas pipeline is assumed to be due to construction work in the vicinity of the pipeline (the pipeline also could fail randomly, but this is a lower frequency failure mode).

Although the CMR Building itself is not served by natural gas, a buried natural gas pipeline runs along its eastern boundary. At this location, the pipeline is a 3-inch (8-centimeter) diameter, 100 psia natural gas pipeline. The specific scenario identified in the CMR SAR involves a failure of the section immediately in front of the CMR Building, which is located about

TABLE G.5.6.1–1.—*Summary Results for Scenario RAD–01*

ALTERNATIVE	ACCIDENT FREQUENCY	SOURCE TERM AND CONSEQUENCES
No Action	1.6 x 10^{-3} per year	Initial source term: 0.13 PE-Ci, elevated thermal release; suspension source term: 0.60 PE-Ci, ground-level release; mean population dose of 72 person-rem excess LCF of 0.036.
Expanded Operations	1.6 x 10^{-3} per year	Same as No Action Alternative.
Reduced Operations	1.6 x 10^{-3} per year	Same as No Action Alternative.
Greener	1.6 x 10^{-3} per year	Same as No Action Alternative.

TABLE G.5.6.1–2.—*Predicted Mean Doses to MEIs for Scenario RAD–01*

MAXIMUM EXPOSED INDIVIDUAL (MEI) DOSE (REM, TEDE)	
MEI LOCATION	**DOSE**
Closest public access (SA): Pajarito Road (100 m)	4.6 x 10^{1}
Special population distance: San Ildefonso Pueblo boundary (400 m)	3.5 x 10^{0}
Special population distance: Mortandad Cave (2,400 m)	1.4 x 10^{-1}
Closest residence: Royal Crest Trailer Park (4,300 m)	5.1 x 10^{-2}
Special population distance: San Ildefonso Pueblo (11,600 m)	1.3 x 10^{-2}

TABLE G.5.6.1–3.—*Predicted Mean Ground Contamination Levels for Scenario RAD–01*

RADIAL DISTANCE	PLUTONIUM-239 GROUND CONCENTRATION (BQ/m^2)
0.0 to 1.0 km	1.1 x 10^{4}
1.0 to 2.0 km	1.2 x 10^{3}
2.0 to 3.0 km	4.7 x 10^{2}
3.0 to 4.0 km	2.6 x 10^{2}
4.0 to 8.0 km	1.3 x 10^{2}
8.0 to 12.0 km	7.6 x 10^{1}
12.0 to 20.0 km	3.5 x 10^{1}
20.0 to 30.0 km	1.7 x 10^{1}
30.0 to 40.0 km	8.4 x 10^{0}
40.0 to 60.0 km	4.2 x 10^{0}
60.0 to 80.0 km	2.4 x 10^{0}

BQ/m^2 = Becquerel per square meter

120 meters from the CMR ventilation intakes located near the spinal corridor of the facility.

This accident scenario is analyzed in the CMR SAR (LANL 1995c). The SAR states that construction potentially leading to this event occurs about every 3 years, and that the conditional probability of damaging the line with construction equipment is 1 x 10^{-3} per construction event (LANL 1995c). This results in an initiating event frequency of 3.3 x 10^{-4} per year.

The SAR includes an event tree for evaluating the frequency of the accident scenario. The event tree accounts for the conditional probability of no external explosion, whether the gas drifts toward or away from the CMR Building, whether the concentration at the intake is above the lower explosive limit (LEL) for natural gas, whether an explosion occurs at the intake, and whether an explosion and/or a fire occur interior to the CMR Building (LANL 1995c). The event tree identifies five separate outcomes leading to an accident:

- External explosion, 1.7 x 10^{-4} per year
- Internal explosion without a fire, 1.6 x 10^{-7} per year
- Explosion at the CMR HVAC intake structure, 1.6 x 10^{-6} per year
- Explosion and fire at the CMR HVAC intake structure, 1.8 x 10^{-7} per year
- Internal explosion with a fire, 1.5 x 10^{-6} per year

Because the internal explosion with a fire is the most likely event having radiological consequences, this is the outcome that is modeled in the SAR and in the SWEIS. The SAR states that an internal explosion is likely to involve only one half of the laboratories in a wing because ventilation in each half of each wing is supplied by a separate supply fan. However, the remainder of the wing could be damaged by fires ignited by the explosion. The explosion also may damage the fire suppression sprinkler system, so no credit is given for containing any fires subsequent to an explosion in a wing. Finally, if the explosion involves a significant portion of a wing, damage to the building structure may occur (such as blowing out the glass block windows and doors), creating an open leak path to the environment (LANL 1995c).

The most vulnerable sections of the CMR Building for this accident are Wings 2, 3, and 7 (and the Administrative Wing) because these wings are located on the east side of the CMR Building nearest the natural gas pipeline. The source term analysis is based on Wing 7 because that wing has the highest administrative limit on dispersible MAR of these three wings (LANL 1995c).

Wing 7 has an administrative limit of 6 kilograms of plutonium-239 equivalent in dispersible form.[1] Of this amount, one kilogram was assumed to be located outside of gloveboxes or sealed metal containers and unprotected from direct blast effects. The release is assumed to be a ground level release (LANL 1995c).

RAD–02 Release Mechanisms

This accident involves consideration of explosion and fire effects on the MAR in the CMR Building. There is a wide variety of radioactive material stored and used in the CMR Building. In the SAR and safety limits documentation, the MAR at the CMR Building is converted to equivalent grams of pure plutonium-239. Although this is an abstraction of what is actually present in the facility, it captures the radiological effects of the diverse MAR. Plutonium-239 in both powder and solution form is considered in this accident.

1. The CMR SAR expresses most radiological releases as equivalent releases of pure plutonium-239. The CMR Building has a variety of different types of MAR, including various plutonium mixtures. Wing limits are expressed in terms of plutonium-249 equivalents, and the SAR accident analysis is largely in the same units.

No Action Alternative Frequency Analysis

The annual frequency for this scenario is quantified as follows:

$$F = F_{PIPE} \times P_{EXTEXP} \times P_{DRIFT} \times P_{LEL} \times P_{INTAKE} \times P_{INTEXP} \times P_{INTFIRE}$$

where:

F = Annual frequency of the scenario

F_{PIPE} = Annual frequency of pipe rupture due to construction

P_{EXTEXP} = Conditional probability of no external explosion at pipe rupture

P_{DRIFT} = Conditional probability of natural gas drifting to HVAC intake

P_{LEL} = Conditional probability of concentration above the LEL at HVAC intake

P_{INTAKE} = Conditional probability of natural gas not exploding at HVAC intake

P_{INTEXP} = Conditional probability of internal explosion of natural gas

$P_{INTFIRE}$ = Conditional probability of internal fire subsequent to explosion

The above equation is evaluated in accordance with the analysis in the SAR. As noted, the frequency of pipe rupture due to construction is 3.3×10^{-4} per year. (This value is consistent with generic industry data, which indicate a pipeline rupture rate of 1.25 per 1,000 miles of pipeline per year [AICE 1994]. Applied to the CMR Building, and taking into account 660 feet [201 meters] of piping in front of CMR [this is the overall width of CMR], this data yields a value of 1.6×10^{-4} per year.) The conditional probability of no external explosion was set at 0.5 (i.e., as likely as not). The conditional probability that the gas drifts toward the CMR Building is based on historical meteorological data for LANL, and is set at 0.285 (a conservative value). The conditional probability that the gas concentration is above the LEL at the intake is evaluated at 0.0769 (based on a calculation from a Gaussian plume dispersion model). The conditional probability of no explosion at the intake is set at 0.5 (i.e., as likely as not). The conditional probability of an internal explosion and the conditional probability of a fire given an explosion, are both set at 0.9 (i.e., very likely).

The frequency equation above is evaluated as follows:

$$F = F_{PIPE} \times P_{EXTEXP} \times P_{DRIFT} \times P_{LEL} \times P_{INTAKE} \times P_{INTEXP} \times P_{INTFIRE}$$

$$= (3.3 \times 10^{-4}) \times 0.5 \times 0.285 \times 0.0769 \times 0.5 \times 0.9 \times 0.9$$

$$= 1.5 \times 10^{-6}$$

Expanded Operations, Reduced Operations, and Greener Alternatives Frequency Analysis

There is no difference in construction frequency across the alternatives. No other factor potentially affecting the conditional probability of any of the other terms of the No Action Alternative frequency equation has been identified. Accordingly, the frequency of 1.5×10^{-6} per year is applicable to the Expanded Operations, Reduced Operations, and Greener Alternatives.

Uncertainties and Sensitivities Affecting the Frequency of RAD–02

The SAR accident scenario progression incorporates several inherent uncertainties that are resolved with the assignment of conservative or representative conditional probabilities using engineering/expert opinion, historical meteorological data, and supporting calculations. The terms of the frequency equation that seem to be the most subject to uncertainty are the two conditional probabilities of explosion: P_{EXTEXP} and P_{INTAKE}.

The conditional probability of no external explosion at the time of the pipeline rupture (P_{EXTEXP}) is probably conservative because the rupture occurs as a result of mechanical damage to the pipeline, which damage (or the engine on the equipment performing the excavation) would be likely to result in ignition of the escaping gas. To illustrate, if this term has a value of 0.1 instead of 0.5, the frequency of the accident would drop to 3 x 10^{-7} per year.

Embedded in the analysis details of this scenario are a number of other assumptions that, if relaxed from their current conservative values, could render the scenario less likely or result in conditions under which the scenario could not progress due to insufficient gas reaching the wing to support an explosion and fire. Among these assumptions are: (1) it is assumed that the supply system can maintain a 100-psia pressure through the 3-inch pipe for the required period of time, even though the system is depressurizing through the break; (2) it is assumed that the flow rate from the broken pipe is equal to the critical flow at the initial system pressure (no credit is taken for pipe segments depressurizing as a result of the break); and (3) the fire suppression sprinkler system within the CMR Building fails 100 percent of the time given an explosion and fire (this is a conservative assumption) (LANL 1995c).

More significantly, however, DOE authorized funding for installation of a flow restriction orifice in the natural gas pipeline, which is the source of the above-described accident. This orifice will limit gas flow in the event of a pipeline break to a value that will preclude the accident from taking place. Thus, upon completion of orifice installation this accident will no longer be credible. The installation was scheduled for Fall 1997 at the time the calculations were made for this accident appendix.

Other Potential Gas Pipeline Accidents at LANL

As a result of the identification of this pipeline failure accident in the CMR SAR, consideration was given to other possible natural gas pipeline accidents at LANL. Four examples have been identified. The TA–18 SAR identified a natural gas explosion for the Hillside Vault (TA–18–26). During the walkdown of this facility, this contributor was screened on the basis of physical implausibility (e.g., the natural gas pipeline is shielded from the Hillside Vault, and there is no active ventilation system nor natural flow process that would result in ingestion of the gas into the Hillside Vault). Similarly, natural gas pipelines are located near TA–55–4. In this case, the construction of TA–55–4 is much more robust than the CMR Building (TA–55–4 has 14-inch-thick reinforced concrete walls), and the ventilation system would remain intact in the event of an explosion (the HVAC system filters are located remotely from the possible site of any explosion inside TA–55–4). In the case of both TSTA and WETF, the natural gas lines are too far from the facilities to present a credible threat. Accordingly, the CMR scenario is considered to be the bounding accident of this type.

Source Term Calculations

The initial source term equation is evaluated four times for four separate source term contributors identified in discussions with CMR facility representatives, and is based on the draft 1996 SAR update for the CMR facility. The four sources of release are MAR in containers and enclosures affected by the explosion, MAR in solution outside an enclosure affected by the explosion, MAR in powder form affected by the fire, and MAR in solution affected by the fire. The initial source term equation is evaluated as follows for these sources:

$$ST_{POWEXP} = MAR \times DR \times ARF \times RF \times LPF$$

$$ST_{POWEXP} = 2{,}500 \times 1 \times 0.005 \times 0.3 \times 1 = 3.8 \text{ grams}$$

$$ST_{SOLEXP} = MAR \times DR \times ARF \times RF \times LPF$$

$$ST_{SOLEXP} = 500 \times 1 \times 1 \times 1 \times 1 = 500 \text{ grams}$$

$$ST_{POWFIRE} = MAR \times DR \times ARF \times RF \times LPF$$

$$ST_{POWFIRE} = 2{,}487 \times 1 \times 0.006 \times 0.01 \times 1 = 0.1 \text{ grams}$$

$$ST_{SOLFIRE} = MAR \times DR \times ARF \times RF \times LPF$$

$$ST_{SOLFIRE} = 3{,}000 \times 1 \times 0.002 \times 1 \times 1 = 6.0 \text{ grams}$$

$$\text{Total Initial Source Term} = ST_{POWEXP} + ST_{SOLEXP} + ST_{POWFIRE} + ST_{SOLFIRE}$$

$$= 3.8 + 500 + 0.1 + 6.0 = 510 \text{ grams}$$

where:

ST = Source Term

ST_{POWEXP} = Source term from powder in containers affected by the explosion

ST_{SOLEXP} = Source term for solution affected by the explosion

$ST_{POWFIRE}$ = Source term for powder affected by the fire

$ST_{SOLFIRE}$ = Source term for the solution affected by the fire

The CMR SAR did not account for source term contribution from suspension subsequent to the explosion and fire. The suspension source term calculation would come from three sources (the fourth possible source, the solution affected by the explosion, has no suspension source term contribution because it was 100 percent released in the initial source term): (1) MAR in containers and enclosures affected by the explosion, (2) MAR in powder form affected by the fire, and (3) MAR in solution affected by the fire. The suspension source term equation is evaluated three times for these sources:

$$RST_{POWEXP} = MAR \times DR \times ARR \times 24 \text{ hrs} \times RF \times LPF$$

$$RST_{POWEXP} = 2{,}496 \times 1 \times (4 \times 10^{-6}/\text{hr}) \times 24 \text{ hrs} \times 1 \times 1$$

$$RST_{POWEXP} = 0.24 \text{ grams}$$

$$RST_{POWFIRE} = MAR \times DR \times ARR \times 24 \text{ hrs} \times RF \times LPF$$

$$RST_{POWFIRE} = 2{,}487 \times 1 \times (4 \times 10^{-6}/\text{hr}) \times 24 \text{ hrs} \times 1 \times 1$$

$$RST_{POWFIRE} = 0.24 \text{ grams}$$

$$RST_{SOLFIRE} = MAR \times DR \times ARR \times 24 \text{ hrs} \times RF \times LPF$$

$$RST_{SOLFIRE} = 2{,}994 \times 1 \times (4 \times 10^{-8}/\text{hr}) \times 24 \text{ hrs} \times 1 \times 1$$

$$RST_{SOLFIRE} = 0.003 \text{ grams}$$

The total suspension source term is the sum of the above contributors, or 0.48 grams.

Suspension source term parameters were selected as follows: (1) based on a homogeneous bed of powder buried under structural debris exposed to ambient conditions or under static conditions within a structure (DOE 1994d); (2) based on the same considerations as (1); and (3) based on a solution indoors, on heterogeneous surfaces, covered with debris or under static conditions (DOE 1994d).

No variations are identified in the progression of the accident or the MAR; thus, the calculated source terms above are considered to represent the accident for all alternatives.

Uncertainties and Sensitivities Affecting the Source Term for RAD–02

The source term for this postulated accident scenario is dominated by the very conservative SAR assumption of an ARF of 1.0 for the solution affected by the explosion. The explosive yield of the explosion inside the wing is not identified in the CMR SAR. DOE Handbook 3010-94 recommends that for detonations in or immediately contiguous to a pool of liquid, a bounding release is assessed to be the mass of inert material equal to the calculated TNT equivalent (DOE 1994d). However, it is not evident that the explosion necessarily occurs in or contiguous to the solution in the case of the CMR event. If the explosion occurs at some distance from the solution and merely spills the solution or shatters the container holding the solution, the source term would be reduced by at least two orders of magnitude, resulting in a release of 5 grams or less, instead of 500 grams.

Because the source term for this accident is completely driven by the assumption of a 100 percent release of the 500 grams of plutonium-239 equivalent in the solution, it is clear that any reduction in this term will directly reduce the overall source term.

Uncertainties in the source term calculation include the extent that the entire wing may be affected by the initial explosion (the SAR assumes only half of wing is involved); the fraction of material that is outside the gloveboxes/enclosures; the fraction of material in powder, solution, or less dispersible forms; and the integrity of the building confinement (e.g., glass block windows). (Building integrity affects the LPF.)

Consequences of RAD–02 for Facility Workers and the Public

The consequences of RAD–02 for facility workers and the public are discussed separately. All workers in Wing 7 at the time of the accident could be severely injured or killed as a result of the dynamics of the explosion, the dynamics and combustion products of the fire, and exposure to plutonium-239 oxide via inhalation. Supply air for the remainder of the building is unfiltered outside air (LANL 1995c). Depending on the dynamics of the explosion release and the direction of the wind at the time of release, it is possible that air contaminated with material released from Wing 7 could be drawn into the remainder of the CMR Building and distributed to the workers in other areas of the building. This would result in inhalation exposures to those workers and contamination of other areas of the CMR Building. Due to the complications of evaluating the impact of the explosion and the resulting emergency response activities, an estimation of the worker doses is not possible with any reliability.

No acute fatalities from radiation exposure to the public are predicted to result from the postulated accident. The mean collective population dose is projected to total 120,000 person-rem (TEDE), resulting in 57 excess LCFs. Mean projected doses for MEIs (and their associated locations) and ground contamination levels are presented in Tables G.5.6.2–2 and G.5.6.2–3, respectively. Table G.5.6.2–1 summarizes the modeling results for RAD–02.

Based on re-evaluation of the meteorological conditions and the frequency of catastrophic brakes, DOE estimates the frequency for this accident now to be less than 10^{-6} (i.e., not credible) (CMR BIO, Appendix J).

G.5.6.3 *RAD–03, Power Excursion Accident with Fast Burst Assembly Outside Kiva #3*

General Scenario Description

The Godiva-IV fast-burst reactor, housed at Kiva #3 at Pajarito Site (TA–18–116), is used in a variety of experiments. This type of reactor is

TABLE G.5.6.2–1.—*Summary of Results for Scenario RAD–02*

ALTERNATIVE	ACCIDENT FREQUENCY	SOURCE TERM AND CONSEQUENCES
No Action	1.5×10^{-6}	504 grams plutonium-239 explosion release (60-second), 6 grams plutonium-239 fire release (2-hour), 0.48 gram plutonium-239 suspension release (24-hour); 120,000 person-rem collective exposure, resulting in 57 excess LCFs.
Expanded Operations	1.5×10^{-6}	Same as No Action Alternative.
Reduced Operations	1.5×10^{-6}	Same as No Action Alternative.
Greener	1.5×10^{-6}	Same as No Action Alternative.

[a]Note: Based on re-evaluation of the meteorological conditions and the frequency of catastrophic brakes, DOE estimates the frequency for this accident now to be $<10^{-6}$ (i.e., not credible) (CMR BIO, Appendix J).

TABLE G.5.6.2–2.—*Predicted Mean Doses to MEIs for Scenario RAD–02*

MAXIMUM EXPOSED INDIVIDUAL (MEI) DOSE (REM, TEDE)	
MEI LOCATION	DOSE
Closest public access (SA): Diamond Road (40 m)[a]	4.0×10^{3}

40.0 to 60.0 km	4.0×10^2
60.0 to 80.0 km	2.2×10^2

BQ/m^2 = Becquerel per square meter

a research tool designed to provide a pulse (or burst) of neutrons for experimental purposes. Accident scenario RAD–03 involves a reactivity excursion that vaporizes a portion of the core and melts the remainder.

Godiva-IV has three 93 percent HEU control rods. One of the rods is used to adjust the burst yield, one is used for achieving a critical state, and the third is rapidly inserted in order to initiate the pulse. A fourth control element, called the safety block, provides a large reactivity shutdown for the assembly.

The assembly is operated by inserting the safety block and adjusting two of the control rods to bring the assembly to a low power steady-state condition called delayed critical. Following the achievement of delayed criticality, the control rod used for yield adjustment is set to an appropriate position for the desired pulse size. The safety block is then partially withdrawn in order to let delayed neutrons decay away for about 15 minutes. The safety block is reinserted, and the pulse rod is rapidly inserted. The control system is designed with interlocks so that each step cannot be taken unless a precise sequence of events occurs (LANL 1996f).

Three principal potential sources of error can be identified in this process: (1) a miscalculation of the desired control-element position and the subsequent element insertion to the wrong position, (2) an incorrect position insertion based on a correct adjustment calculation, and (3) an error due to a faulty position indicator. In the first two cases, two errors are necessary. In the first case, two operators perform the calculation independently, making it unlikely that the same incorrect position could be calculated. (In addition, the operators have a logbook available to consult for past control element settings to produce the required pulse.) In the second case, the senior operator checks the final adjustment (LANL 1996f).

The effect of an operator error in the control-element adjustment could be either a larger- or smaller-than-planned superprompt critical pulse. The magnitude of the pulse is dependent on the magnitude of the error. A conditional probability factor is applied to recognize that only a small fraction of the wide range of potential pulse sizes would actually lead to reactor damage.

Another potential scenario for initiating an over-sized pulse is based upon inadvertent movement of an experiment near the reactor during the pulse operations. All equipment installed in the immediate vicinity of Godiva-IV is required to be structurally stable without support by guy wires, unattached props, or other means. However, the possibility of movement cannot be completely eliminated because the cause of movement is as varied as the experiments themselves. Because movable and remotely controllable experiments are carefully controlled and executed to avoid such movement, the most likely cause of movement is a gravity fall of the experiment (LANL 1996f). Experiment movement during the pre-pulse waiting period is not apparent through observable system parameters (LANL 1996f).

The inadvertent movement of an experiment during the waiting period could change the reactivity of the system, which establishes the rate at which the chain reaction would occur. Depending on the magnitude of the change in the experimental setup, the additional reactivity could produce a substantial increase in the energy released during the pulse. The additional energy could be sufficient to vaporize material in the reactor. The amount of energy introduced to the system is estimated at 40.3 megajoules, which is large enough to cause fracturing, melting, or boiling of the fissile material. The vaporized material has an estimated energy of 10 percent of the total energy, or 4.0 megajoules. Thus, the vaporized material has the potential to damage the core and release an abnormal amount of fission products to the kiva building.

This accident scenario was analyzed in the TA–18 SAR. No accident sequence frequency was estimated or calculated in the SAR, nor was a frequency bin assignment made. Rather, the SAR stated that all of the accidents analyzed were incredible, implying a frequency of less than 10^{-6} per year.

The SAR source term was estimated based on the assumption that 10 percent of the 66 kilograms of uranium metal is volatilized into transportable aerosol. The release of fission products due to the pulse operation also was taken into consideration (LANL 1996f). The release fractions for fission products are specified as 100 percent for noble gases, 25 percent for halogens (e.g., iodine), and 1 percent for “semi-volatiles” (LANL 1996f). (The SAR does not describe what happens to the 90 percent of the core that does not vaporize. Analysis of a similar scenario involving the SPR-III fast-burst reactor at SNL suggests that the remainder of the core melts. Whether this assessment is fully applicable to Godiva-IV is unclear; however, the analysis below errs on the side of conservatism, and the source term reflects the melting of the remainder of the fuel.)

No Action Alternative Frequency Analysis

This accident requires an unanticipated reactivity insertion being introduced during the time between the shutdown of the delayed-critical setup operation and the insertion of the burst reactivity. This could occur in one of two ways: (1) by operator error or a malfunction of the control systems in adding the burst reactivity increment or (2) by addition of reactivity from movement or reconfiguration of the experiment between shutdown of the delayed-critical setup operation and the insertion of the burst reactivity (LANL 1996f).

Operator error or malfunction of the control systems leading to addition to the planned burst increment can happen in three ways: (1) a miscalculation of the desired control-element position and the subsequent element insertion to the wrong position, (2) an incorrect position insertion based on a correct adjustment calculation, and (3) an error due to a faulty position indicator.

Miscalculation of Control-Element Position. Miscalculation of the control element position requires two independent errors. In addition, the errors have to be sufficiently severe to result in an extreme power excursion. The frequency of this contributor to RAD–03 can be calculated as follows:

$$F_{HEPCALC} = F_{EXP} \times H_{MISCALC} \times H_{MISCALC} \times C_{EXTREME}$$

where:

$F_{HEPCALC}$ = Frequency of the human error in calculation contribution to RAD–03

F_{EXP} = Annual number of Godiva-IV experiments performed

$H_{MISCALC}$ = Human error probability for calculational error

$C_{EXTREME}$ = Conditional probability of a large calculational error

The annual number of Godiva-IV runs for the No Action Alternative is reported to be a maximum of 80 (PC 1997).

The HEP for a miscalculation is generally in the range of 10^{-4} to 10^{-2} (Mahn et al. 1995 and Swain and Guttmann 1983). A value in the middle of that range is judged to be appropriate, considering that the most likely cause of the calculational error is entering an incorrect datum into a calculator/computer.

In addition, it should be noted that not all calculational errors are of equal severity in terms of their ability to result in scenario RAD–03. The conditional probability of such a severe calculational error, especially considering that the results can be checked with the logbook of previous burst calculations, is judged to be less than 0.01 (1 percent). (Considering the conduct of experiments under specially prepared test plans and experiment plans, an even lower value could be appropriate.)

The above equation can be solved as follows:

$$F_{HEPCALC} = F_{EXP} \text{ x } H_{MISCALC} \text{ x } H_{MISCALC} \text{ x } C_{EXTREME}$$

$$= 80 \text{ x } 0.001 \text{ x } 0.001 \text{ x } 0.01$$

$$= 8 \text{ x } 10^{-7} \text{ per year}$$

Incorrect Position Insertion. This contributor to power excursions requires two human errors: the incorrect positioning action, as well as the failure of the crew chief to detect this incorrect positioning. In addition, the error must be sufficiently extreme such that the large power excursion for RAD–03 occurs.

The frequency of this contributor to RAD–03 can be calculated using the following equation:

$$F_{HEPPOS} = F_{EXP} \text{ x } H_{POS} \text{ x } H_{CHK} \text{ x } C_{EXTREME}$$

where:

F_{HEPPOS} = Frequency of the human error in mispositioning the controller

F_{EXP} = Annual number of Godiva-IV experiments performed

H_{POS} = HEP for calculational error

H_{CHK1} = HEP, check of position by supervisor

H_{CHK2} = HEP, check of position against log of previous experiments

$C_{EXTREME}$ = Conditional probability of a large calculational error

As indicated above, the annual number of Godiva-IV runs for the No Action Alternative is a maximum of 80. The mean HEP for setting a rotary control to the wrong position is 0.001 per demand (Swain and Guttmann 1983). The HEP for the crew chief failing to detect the incorrect position indication is 0.05 per demand, based on checking that involves active participation in special measurements (Swain and Guttmann 1983). Finally, the position indication would be checked against previous experiments, providing one last opportunity to correct the error. The likelihood that this check will fail to correct the error is taken as 0.05 as well. Once the position is incorrectly set and verified, there is no additional opportunity to correct the error.

The most likely incorrect position insertion is a small deviation from normal. Such a small deviation would not yield a large enough reactivity insertion to result in accident RAD–03. Only a very large deviation would produce this accident. It is judged that the conditional probability of the error being large enough to produce the accident scenario is likely to be in the range of 0.01 per error (that is, given an error is made, there is a 1 percent chance that the error will be of a sufficiently large magnitude to result in the accident).

The above equation can be solved as follows:

$$F_{HEPPOS} = F_{EXP} \times H_{POS} \times H_{CHK1} \times H_{CHK2} \times C_{EXTREME}$$

$$= 80 \times 0.001 \times 0.05 \times 0.05 \times 0.01$$

$$= 2 \times 10^{-6} \text{ per year}$$

Faulty Position Indication. The frequency of this contributor to RAD–03 can be calculated by the following equation:

$$F_{IND} = F_{EXP} \times F_{RATE} \times D_{EXP} \times H_{DETECT}$$

where:

F_{IND} = Annual frequency of faulty indicator contributor to RAD–03

F_{EXP} = Annual number of Godiva-IV experiments performed

F_{RATE} = Failure rate of the indicator per hour

D_{EXP} = Duration of experiment in hours (time in which indicator must function)

H_{DETECT} = HEP for failure of operations staff to detect the failed indicator

The annual number of Godiva-IV runs for the No Action Alternative is a maximum of 80. The type of position indicator used for the Godiva-IV machine is not specified in the SAR. Typical nuclear industry failure rates for indicator devices are in the range of 2×10^{-7} to 2×10^{-6} per hour (INEL 1990); a value in the middle of this range is assumed (7×10^{-7} per hour). It is assumed that the position indicator must read accurately for 1 hour.

The HEP for failure of the operations staff to detect the failed indicator is estimated at 0.01 per demand (based on an analogy to detecting a failed valve that has neither position indication nor a rising stem to identify the failed state) (Swain and Guttmann1983).

The above equation can now be solved as follows:

$$F_{IND} = F_{EXP} \times F_{RATE} \times D_{EXP} \times H_{DETECT}$$

$$F_{IND} = 80 \times (7 \times 10^{-7}) \times 1 \times 0.01$$

$$F_{IND} = 6 \times 10^{-7} \text{ per year}$$

Sum Total Frequency for RAD–03

The sum total frequency of RAD–03 is obtained by adding the frequency of the three contributing events as follows:

$$F_{TOTAL} = F_{HEPCALC} + F_{HEPPOS} + F_{IND}$$

$$= (8 \times 10^{-7}) + (2 \times 10^{-6}) + (6 \times 10^{-7})$$

$$= 3.4 \times 10^{-6} \text{ per year}$$

Expanded Operations Alternative Frequency Analysis

The total number of pulse operations at Godiva-IV and Skua will increase for the Expanded Operations Alternative to 120 to 150 per year. We have assumed that the relative proportion of Godiva-IV versus Skua bursts will remain constant, and accordingly, have increased the frequency of RAD–03 by a factor of 1.25, to 4.3×10^{-6} per year.

Reduced Operations and Greener Alternatives Frequency Analysis

The frequency of Godiva-IV runs for the Reduced Operations and Greener Alternatives is the same as for the No Action Alternative. Thus, the frequency of accidents is the same for the Reduced Operations and Greener Alternatives as it is for the No Action Alternative.

Uncertainties and Sensitivities Affecting the Frequency of RAD–03

The frequency of RAD–03 is sensitive to the assumptions made above regarding the likelihood of various types of human errors and equipment failures.

Source Term Calculations

The accident being considered here assumes that the Godiva-IV assembly is being operated outside the confines of Kiva #3, which is occasionally done for direct radiation dose measurements to remove the effects of reflected and backscattered radiation (LANL 1996f). The SAR assumes that 10 percent of the core (6.6 kilograms of highly enriched uranium [HEU]) is vaporized, and also models the fission product release as a result of core damage and vaporization. The release fractions assumed are consistent with melting of the nonvaporized portion of the core.

The general initial source term equation will be used to evaluate the additional contribution to the source term arising from melting of the remaining 59.4 kilograms of the core (66 kilograms less 6.6 kilograms vaporized). The MAR is 66 kilograms. The damage ratio is 0.9 (the fraction of the core not vaporized). The ARF and RF values are selected based on free-fall of molten metal drops, with ARF = 0.01 and RF = 1.0 (DOE 1994d). The LPF is 1 because the release occurs outdoors. This results in an additional airborne release of HEU of:

Initial Source Term = MAR x DR x ARF x RF x LPF

= 66,000 x 0.9 x 0.01 x 1 x 1

= 594 grams

The total initial source term for HEU is thus 6,600 grams + 594 grams, or a total of 7,194 grams.

The suspension source term was not calculated in the TA–18 SAR. Most of the HEU not participating in the initial release would be expected to “freeze” and not be available for release. However, this is not addressed in DOE Handbook 3010-94 (DOE 1994d). Accordingly, a conservative suspension release will be calculated by assuming that the HEU not initially released is deposited on the ground as a powder.

The suspension source term is calculated as follows:

Suspension Source Term = MAR x DR x ARR/hr x 24 hrs x RF x LPF

= (66,000 - 7,194) x 1 x 0.00004 x 24 hrs x 1 x 1

= 56 grams

The release of fission products also occurs in this accident. A screening analysis was conducted of the released fission products identified by the SAR. For a release of this nature, occurring during a short fission pulse, the large majority of fission products have very short half-lives (on the order of 0.21 seconds to 3.15 minutes), and decay primarily by beta and gamma emission. The SAR analysis assigned an average dose-rate conversion factor for air immersion (cloudshine) of 4,000 millirem-cubic meters per microcurie-year. Based on the SAR radionuclide release quantities and the dose-rate conversion factor values, the dominant radionuclides were identified. Decay of the risk-dominant radionuclides to more stable progeny was evaluated. Comparison of the decay product quantities and dose conversion factors with the highly enriched uranium source term values indicated that the fission products provide a negligible contribution to the total dose from internal exposure pathways. Consequently, doses resulting from internal exposure pathways for fission products were not modeled. Doses resulting from the external exposure pathway (air immersion) for fission products (4.68 x 10^5 curies) were estimated using the SAR determined average dose-rate conversion factor of 4,000 millirem-cubic meters per microcurie-year. There are no differences in source terms across the alternatives.

Uncertainties and Sensitivities Affecting the Source Term for RAD–03

The major uncertainties in the source term calculation are the 10 percent assumed vaporization of HEU as a result of the power excursion and the conservative modeling of suspension based on HEU as a powder.

Consequences of RAD–03 for Facility Workers and the Public

The consequences for facility workers and the public are discussed separately. Operations with Godiva-IV located outside Kiva #3 would be conducted during off hours with road closure controls in effect. Staffing at TA–18 would be expected to be less than during normal workday operations. The Kiva #3 control room is located 669 feet (204 meters) from the kiva (LANL 1996f). The walls of the control room are such that 40 percent attenuation of gamma doses from the outside is accomplished (LANL 1996f). In the event of an accident, ventilation systems for the control building (TA–18–30) would be secured. Air exchange with the outside would be a function of wind loading and diffusion in and around wall and ceiling penetrations (LANL 1996f). However, the ventilation system for the control building is not protected by HEPA filters (LANL 1996f).

No acute fatalities are predicted to result from the postulated accident. The mean collective population dose is projected to total 110 person-rem (TEDE), resulting in 0.06 excess fatal cancers. Mean projected doses for MEIs (and their associated locations) and ground contamination levels are presented in Tables G.5.6.3–2 and G.5.6.3–3, respectively. Table G.5.6.3–1 summarizes the modeling results for RAD–03.

G.5.6.4 *RAD–04, Inadvertent Detonation of Plutonium-Containing Assembly at DARHT*

General Scenario Description

The DARHT Facility is under construction at R site in TA–15. When completed, the facility will provide dual-axis radiographic images at the highest penetration and resolution available for the study of materials and devices under hydrodynamic conditions. DARHT was the subject of a DOE Environmental Impact Statement (DOE 1995a) and subsequent Record of Decision. The DARHT EIS included analysis of potential accidents, including bounding accidents that were selected and evaluated on a what-if basis (DOE 1995a) based on potential consequences, with little or no consideration of the frequency of occurrence, though the likelihood of occurrence would be small; in related safety analyses these accidents have been evaluated to be not credible (probability less than 10^{-6} per year) and they have been similarly identified in this SWEIS. Scenario RAD–04 represents the inadvertent uncontained detonation of plutonium-containing assembly that was evaluated as the bounding accident for all alternatives in the DARHT EIS, and is included on a similar what-if basis. Scenario RAD–11 represents the other such plutonium accident evaluated in the DARHT EIS on a what-if basis, the breach of a double-walled containment vessel.

As explained in greater detail in the DARHT EIS, the accident scenario RAD–04 involves the inadvertent detonation of high explosives and subsequent dispersal of plutonium from a plutonium-containing assembly intended for a dynamic experiment to be radiographed at DARHT (or its existing predecessor facility located a short distance away, Pulsed High-Energy Radiation Machine Emitting X-Rays

TABLE G.5.6.3–1.—*Summary Results for Scenario RAD–03*

ALTERNATIVE	ACCIDENT FREQUENCY	SOURCE TERM AND CONSEQUENCES
No Action	3.4×10^{-6}	7,194 grams of HEU initially, along with 4.68×10^{5} Ci fission products; three, 8-hour suspension releases of 18.7 grams each; all ground level releases; results in 110 person-rem integrated population exposure and 0.06 excess LCFs.
Expanded Operations	4.3×10^{-6}	Same as No Action Alternative.
Reduced Operations	3.4×10^{-6}	Same as No Action Alternative.
Greener	3.4×10^{-6}	Same as No Action Alternative.

60.0 to 80.0 km	8.1×10^{-1}

BQ/m^2 = Becquerel per square meter

(PHERMEX); continued operation of PHERMEX was considered under the No Action Alternative in the DARHT EIS). PHERMEX has performed, and when completed DARHT will perform, radiography of both hydrodynamic tests and dynamic experiments (DOE 1995a).

A hydrodynamic test is a dynamic, integrated systems test of a mockup nuclear package, in which simulant materials are used to replace the fissile materials. Dynamic experiments provide information on the basic physics of materials or characterize the physical changes or motions of materials under the influence of high explosive detonations. Some dynamic experiments contain plutonium in order to obtain needed information and understanding associated with nuclear weapons aging and continued assurance of weapon safety and performance (DOE 1995a). As a matter of policy, these experiments will always be conducted inside a double-walled steel containment system consisting of an inner confinement vessel and an outer safety vessel to prevent plutonium release; furthermore, the experiments will always be arranged and conducted in such a manner that a nuclear explosion could not result (DOE 1995a). Though some hundreds of dynamic experiments may be conducted per year, only a small number will contain plutonium (LANL 1996m).

For the RAD–04 scenario, in addition to immediate worker deaths due to the high explosive blast, human health impacts to the public are dominated by the explosive aerosolization and atmospheric dispersal of plutonium and the subsequent public exposure. Impact analysis for this SWEIS is taken directly from the DARHT EIS analysis, upon which DOE has received comment from the public; other agencies; and state, local, and tribal governments. Up to tens of excess LCFs based on a 50-year committed dose could result from this hypothetical scenario, depending on the population sector assumed to be exposed due to extant winds. For the convenience of the public and the decision maker, some of that information is also directly reproduced here and referenced to the DARHT EIS. The methodology and all impacts associated with this hypothetical, uncontained detonation scenario are principally contained in Chapter 5 and Appendixes H, I, and J of that EIS; additional information is contained in a classified appendix.

No Action Alternative Frequency Analysis

As discussed above, this accident analysis was presented in the DARHT EIS on a “what-if” basis. What-if means that regardless of the actual ability for an initiating event or accident progression to occur, the consequences of an assumed event shall be considered. For this case, the event is an uncontained detonation of a plutonium-containing assembly at the DARHT facility.

The accident was estimated to be incredible, but several related safety studies were underway when the DARHT EIS was being completed. These studies have since been completed. The studies also support the initial estimation that the accident would be incredible (probability less than 10^{-6} per year). RAD–11 is the mitigated accident where the container is breached, and its probability is also less than 10^{-6} per year. These probabilities mean that, for these accidents, neither is expected to occur.

Nevertheless, this scenario is presented along with several other incredible accidents. These scenarios tend to demonstrate the importance and effectiveness of controls and engineering standards. The what-if scenario generally corresponds to the case where controls are assumed to have failed, and an initiating event that could cause such a consequence is assumed to be possible. When estimates are made about the probability of an initiating event occurring or the failure of multiple control barriers, then the frequencies of an inadvertent detonation become very small. The expected outcome for these experiments is a contained detonation, with a very limited probability that an inadvertent detonation will occur.

Expanded Operations, Reduced Operations, and Greener Alternatives Frequency Analysis

Because the activities at DARHT do not charge across alternatives, the frequency of this scenario remains less than 10^{-6} per year.

Source Term Calculations

Detonation of an experimental assembly results in the aerosolization and potential atmospheric dispersion of a portion of the materials contained within the assembly. As described in the DARHT EIS (DOE 1995a), analysis of this hypothetical accident is documented in a classified appendix to that EIS. While the resulting impacts, as well as unclassified calculations, assumption, and modeling methods are contained in the unclassified sections of the EIS, some details of such experiments, including some associated with the source terms for this accident scenario, are classified.

Consequences of RAD–04 for Facility Workers and the Public

Impacts to workers, noninvolved workers, public populations, and MEIs were described in the DARHT EIS. For involved workers at and around the firing site, the number of workers (and observers) when explosives are present is limited to 15; under an inadvertent detonation scenario, all of these individuals could be killed (DOE 1995a).

Predominant human health impacts to noninvolved workers or the public would stem from exposure to aerosolized and dispersed material. Impacts to noninvolved workers at distances of 2,500 and 1,300 feet (750 and 400 meters) were evaluated (DOE 1995a). Doses to noninvolved workers were estimated to be 90 rem and 160 rem for a worker at 2,500 and 1,300 feet (750 and 400 meters), respectively; corresponding probability of an excess LCF would be 0.06 and 0.04, respectively, for those individuals. LANL administratively controls access to explosives areas by noninvolved individuals and has a set of established hazard radii for protection of personnel from fragment injury from explosives experiments, based on DOE principles. It was estimated that a noninvolved worker would likely be no closer than 2,500 feet (750 meters). The public MEI located at State Road 4 was calculated to receive 76 rem, with a resulting probability of an excess LCF of 0.04 (DOE 1995a). The impacts to workers and the public MEI were summarized in Table G–10 of the DARHT EIS, which is reproduced here as Table G.5.6.4–1 for the convenience of the public. This table also includes information pertinent to the containment breach scenario RAD–11.

TABLE G.5.6.4–1.—*DARHT EIS Hypothetical Impacts to Workers and the Public from Postulated Accidents Involving Plutonium*

AFFECTED CATEGORY	INADVERTENT DETONATION		CONTAINMENT BREACH	
	DOSE (REM)	MAXIMUM PROBABILITY OF EXCESS LCFS	DOSE (REM)	MAXIMUM PROBABILITY OF EXCESS LCFS
Workers —	___[a]	NA	no impact	no impact
Noninvolved Workers				
750 m	90	0.04	20	0.009
400 m	160	0.06	60	0.02
Public MEI	76	0.04	14	0.007

[a] No radiological impact estimated; up to 15 fatalities could result from explosion blast effects.
[b] NA = Not applicable

The population exposure for the most populated sector (which includes White Rock and Santa Fe) was estimated to be between 9,000 and 24,000 person-rem for 50th and 95th percentile meteorological conditions, respectively, resulting in 5 to 12 excess LCFs (DOE 1995a). While diffusion of material across an entire directional sector was taken into account, it was assumed that all of the community populations were located at or near to the plume center line, a conservative assumption that results in an overestimate of exposures (DOE 1995a).

Population dose and impacts to other communities also were calculated using the conservative assumption that the plume passed directly over and through each hypothetically affected community (though they are generally in different directions). Because of its closeness to LANL, Los Alamos could be one of the most affected communities if the plume passed its way, calculated to receive up to 45,100 person-rem resulting in up to 22 excess LCFs (for 95th percentile meteorology). (This value could be overestimated because the airborne plume would be relatively narrow at this distance and may miss much of the population.) Other communities, including Española and the Jemez and Santa Clara Pueblos, could receive sufficient population doses under the specific exposure conditions assumed that some excess LCFs could occur. The impacts to public populations were summarized in tables G-11 and G-12 of the DARHT EIS, which are reproduced here as Tables G.5.6.4–2 and G.5.6.4–3 for the convenience of the public. (Table G.5.6.4–2 also includes information pertinent to the containment breach scenario RAD–11.) In addition, Figure 5–1 from the DARHT EIS, which shows the most populated sector and the distribution of minority population, also is reproduced here (as Figure G.5.6.4–1).

The DARHT analysis (DOE 1995a) evaluated all significant impacts from this accident, including dispersal and human health impacts from other materials in the dynamic experiment assembly; it evaluated impacts to the public MEI, to the population, noninvolved workers, and involved workers. It used a conservative 95th percentile meteorology to various geographic population sectors, based on recent historical wind data, in calculating impacts. For atmospheric dispersion and resulting dose consequences, the DARHT EIS employed the GENII code, while other analyses in this SWEIS uses the MACCS 2 code; both codes are established for such use. The DARHT EIS also considered some different approaches to

TABLE G.5.6.4–2.—*DARHT EIS Hypothetical Impacts to the Most Populated Sector from Postulated Accidents Involving Plutonium*

ATMOSPHERIC DISPERSION ASSUMPTION	INADVERTENT DETONATION		CONTAINMENT BREACH	
	POPULATION DOSE (PERSON-REM)	NUMBER OF EXCESS LCFS	POPULATION DOSE (PERSON-REM)	NUMBER OF EXCESS LCFS
50th percentile	9,000	5	210	0 (0.1)
95th percentile	24,000	12	560	0 (0.3)

Note: The communities of Santa Fe and White Rock are included within the population of this sector.

dispersion modeling, the results of which varied by less than a factor of 10 uncertainty in atmospheric dispersion model results that the EIS acknowledged to be ordinarily assumed for such models (DOE 1995a). As does this SWEIS, the DARHT EIS incorporated various factors and approximations to assure impact analyses are conservative, though not unduly so. Therefore, differences in models and methodology from the DARHT EIS do not affect the evaluation of the alternatives in this SWEIS.

G.5.6.5 *RAD–05, Aircraft Crash and Tritium Release at TSTA/ TSFF*

General Scenario Description

The Tritium Science and Fabrication Facility (TSFF, TA–21–209) and the Tritium Systems Test Assembly (TSTA, TA–21–155) are two DOE Hazard Category 2 nonreactor nuclear facilities that handle tritium. The buildings are located in TA–21, 0.4 mile (0.6 kilometer) from and parallel to the runway of Los Alamos Airport. The buildings are about 75 feet (23 meters) apart with an intervening building (TA–21–152) separating the two facilities.

The accident scenario for RAD–05 involves an aircraft crash into TSFF and/or TSTA. Initially, it was thought that these two facilities could be modeled as a single target. However, refinement of the modeling indicated that tritium was actually likely to be present only in a small fraction of the total floor area of these two facilities. Accordingly, and in conformance with DOE Standard 3014-96 (DOE 1996c), the targets were modeled separately. Perforation/ explosion was not considered to be possible at these facilities due to the lack of explosive materials. Accordingly, the scenario was limited to perforation/fire considerations. Further refinement of the crash scenarios is possible to take into account shielding of the two buildings with respect to one another, which would reduce the crash frequencies. However, even conservatively assuming the entire facility inventory is released in oxide form, the dose consequences are somewhat modest (24 person-rem integrated population exposure and 0.0093 excess LCFs) compared with other accident scenarios evaluated in the LANL SWEIS, and further refinement was deemed to be unnecessary.

No Action Alternative Frequency Analysis

The air space above LANL is restricted up to 14,000 feet (4,270 meters), designated as Restricted Airspace R-5101 (LANL 1996c). However, DOE Standard 3014-96 states that once an in-flight mishap does occur, with eventual loss of control, there is nothing to prevent a disabled aircraft from crashing into any location, even within a restricted airspace area (DOE 1996c). The estimated frequency for perforation/fire for TSTA and TSFF is estimated at 3.8 x 10^{-6} and 5.3 x 10^{-6} per year, respectively.

Expanded Operations, Reduced Operations, and Greener Alternatives Frequency Analysis

Aircraft crash rates in the vicinity of LANL are not significantly associated with the level of activity at LANL. Accordingly, the frequency of aircraft crash does not vary by alternative.

Uncertainties and Sensitivities Affecting the Frequency of RAD–05

There is a large number of data required in order to perform the DOE Standard 3014-96 calculations. In addition, the standard itself requires the use of numerous equations that are recognized to be approximations (DOE 1996c).

Perhaps the most important uncertainty is the assumption (embedded in the standard) that a skidding aircraft will impact a facility with the same velocity it had when it began the skid. This results in a conservative impact velocity because no credit is taken for drag, friction, impact with objects between the impact point and the facility, and so on. Other conservatisms include the assumption that the entire aircraft engine is the penetrating missile of concern. This is conservative because most of the fan shroud would tear away when striking the facility, leaving the engine shaft as the secondary penetrator.

Source Term Calculations

It was conservatively assumed that the entire inventory of the facility of interest (either TSTA or TSFF) would be released in oxide form in the event of an aircraft crash, due to fire. The MAR value for TSFF is 100 grams of tritium in process and 100 grams of tritium in storage in containers in vaults (Valentine and Pendergrass 1997). The MAR for TSTA is 200 grams (except for the Reduced Operations Alternative, for which the MAR is 150 grams). Only one building is assumed to be destroyed in a crash due to the presence of the intervening structure (TA–21–152) between TSFF and TSTA. It is assumed that in all cases the inventory of the building that is destroyed is 200 grams of tritium, released in oxide form. With the exception of TSTA in the Reduced Operations Alternative, the inventory of the destroyed building will be 200 grams. Because in the Reduced Operations Alternative there is as good a chance of hitting a 200 gram inventory building as there is hitting a 150 gram inventory building, modeling the release as 200 grams is reasonable. The standard DOE Handbook 3010-94 source term equation was employed in the source term calculation. The DR is 1 (building destruction due to explosion and fire). The ARF and RF are 1 for tritium. The LPF is also 1 due to the breach of the building by the aircraft penetration and explosion. As a result, the source term equation reduces to the MAR.

Uncertainties and Sensitivities Affecting the Source Term for RAD–05

It is assumed that there is 100 percent conversion of tritium gas to tritium oxide. This is conservative but feasible.

Consequences of RAD–05 for Facility Workers and the Public

Worker consequences and public consequences are discussed separately. A detailed worker consequence analysis was not performed; however, the following observations are made regarding the aircraft crash scenario:

- An aircraft crash that destroys the facility is assumed to result in the death of all workers in the building.
- Workers in adjacent facilities (such as the noninvolved tritium building and the intervening structure) may be injured due to flying debris from the explosion or aircraft crash, and could also be exposed to tritium oxide.

No radiation-related acute fatalities are predicted to result from the accident. The mean collective population dose is projected to total 24 person-rem (TEDE), resulting in 0.012 excess LCFs. Mean projected doses for MEIs (and their associated locations) are presented in Table G.5.6.5–2. The tritium oxide source term does not result in ground contamination. Table G.5.6.5–1 summarizes the modeling results for RAD–05.

G.5.6.6 *RAD–06, Aircraft Crash and Plutonium Release from RAMROD*

General Scenario Description

The Radioactive Materials Research, Operations, and Demonstration (RAMROD) Facility is located at TA–50–37, the site of the former treatment demonstration incineration facility. Although the RAMROD Facility has

TABLE G.5.6.5–1.—*Summary Results for Scenario RAD–05*

ALTERNATIVE	ACCIDENT FREQUENCY	SOURCE TERM AND CONSEQUENCES
No Action	3.8×10^{-6} (TSTA) 5.3×10^{-6} (TSFF)	200 grams of tritium as oxide; integrated population exposure of 24 person-rem, 0.012 excess LCFs.
Expanded Operations	3.8×10^{-6} (TSTA) 5.3×10^{-6} (TSFF)	Same as No Action Alternative.
Reduced Operations	3.8×10^{-6} (TSTA) 5.3×10^{-6} (TSFF)	Same as No Action Alternative.[a]
Greener	3.8×10^{-6} (TSTA) 5.3×10^{-6} (TSFF)	Same as No Action Alternative.

[a]For the Reduced Operations Alternative, the inventory at TSTA is reduced by 25 percent. The bounding consequence of 24 person-rem from a 200 gram release at TSFF is assumed.

TABLE G.5.6.5–2.—*Predicted Mean Doses to MEIs for Scenario RAD–05*

MAXIMUM EXPOSED INDIVIDUAL (MEI) DOSE (REM, TEDE)	
MEI LOCATION	**DOSE**
Closest public access: Access road to facility (10 m)	(see note)
Closest routine public access: Route 502 (360 m)	1.2×10^{-2}
Closest special population: Los Alamos Airport (780 m)	2.0×10^{-2}
Closest residence (TSFF SAR MEI location): Los Alamos (970 m)	1.8×10^{-2}
Special population distance: San Ildefonso Pueblo boundary (2,300 m)	3.3×10^{-2}
Special population distance: San Ildefonso Pueblo (14,000 m)	1.2×10^{-2}

Note: For the given modeling conditions, the postulated elevated release would pass over this location before touching the ground. However, in reality this location would probably be directly impacted by the aircraft crash, and an estimation of dose would be impractical and of limited usefulness.

several uses, the most significant from the standpoint of health and safety consequences in the event of an accident is the visual characterization of TRU waste. SWEIS accident scenario RAD–06 involves an aircraft crash at RAMROD, resulting in a fire that causes the release of plutonium from TRU waste. Most of the release results from the combustible portion of the waste, which is stored in DOT Type A 55-gallon drum containers when it is not being visually examined in glovebox lines in RAMROD.

This accident is presented to provide comparisons of the aircraft crash results across LANL. The accident would have screened out based on the frequency of occurrence for such events.

Source Term Calculations

The source term calculation assumed a fire following the aircraft crash. Two aircraft types account for about 98.5 percent of the total aircraft crash frequency at RAMROD: multiple-engine piston aircraft and small military aircraft. In order to evaluate the fire potential of these aircraft, the bounding fuel load (LLNL 1996) was based on a review of the characteristics of the aircraft in these classes as identified in the supporting documentation for DOE Standard 3014-96. The aircraft selected for these classes are: (1) the Cessna Titan line, with a fuel load of 413 gallons (1,564 liters), for the multiple-engine piston aircraft; and (2) the F-16C, with a fuel load of 1,801 gallons (6,819 liters) for the small military aircraft (LLNL 1996).

In order to quantify the burn area resulting from a spill of aircraft fuel and its subsequent combustion, guidance from the Rocky Flats Risk Assessment Guide was followed that provides an estimate of a 250 square-foot (23 square-meter) burn area per 50 gallons of fuel burned (RFETS 1994). Burn areas were calculated as follows for the three significant classes of aircraft:

$$A_{BURN} = (F_{LOAD}/50) \times 250 \text{ ft}^2$$

where:

A_{BURN} = Burn area in square feet

F_{LOAD} = Aircraft fuel load in gallons

The estimated burn area for each of the significant aircraft types can now be calculated:

Multiple-Engine Piston Aircraft:

$$A_{BURN} = (F_{LOAD}/50) \times 250 \text{ ft}^2$$

$$A_{BURN} = (413/50) \times 250 \text{ ft}^2$$

$$A_{BURN} = 2{,}065 \text{ ft}^2$$

Small Military Aircraft:

$$A_{BURN} = (F_{LOAD}/50) \times 250 \text{ ft}^2$$

$$A_{BURN} = (1{,}801/50) \times 250 \text{ ft}^2$$

$$A_{BURN} = 9{,}005 \text{ ft}^2$$

For RAMROD, the overall area of the facility (first floor) is 15,690 square feet (1,458 square meters). The burn areas identified above represent the following percentages of the RAMROD building:

- Multiple-engine piston aircraft = 13.2 percent
- Small military aircraft = 57.4 percent

The MAR for RAMROD consists of 479 containers. These consist of 48 containers containing 75 PE-Ci each (according to the TA–54 SAR, 1 percent of LANL TRU waste containers have an inventory of 75 PE-Ci) (LANL 1995i), and 431 containers containing an average of 12 PE-Ci each (LANL 1996n). Thus, the total inventory is (48 x 75) + (431 x 12) = 3,600 + 5,172 = 8,772 PE-Ci. Given the units used in the RAMROD SAR, releases to the environment will be expressed in grams of pure plutonium-239, rather than in grams of weapons-grade or heat-source plutonium. (The low-level mixed waste inventory is not included because the contribution to the PE-Ci inventory is trivial.)

The initial source term equation must be quantified separately for each type of aircraft contributing significantly to the crash frequency due to the difference in the impacted area of the facility. Due to the random nature of aircraft crashes, no specific directionality is associated with the crashes. The damage ratio will be expressed as the product of the percentage of the facility floor area burned in a fire (which will be assumed to equate to the fraction of the inventory affected by fire) and the fraction of the TRU waste inventory that is typically present in combustible form (0.35). This approach is equivalent to "smearing" the inventory evenly across the floor area of the building.

It is recognized that some crashes could result in a fire without affecting MAR; whereas, other crashes could burn a quantity of waste that is in excess of the fraction the floor area affected by the burn. However, the approach adopted above is believed to yield a reasonable result that is considered to be representative of the average that would result from a large number of crashes.

The ARF and RF values are selected from DOE Handbook 3010-94 and are based on the bounding values for packaged mixed combustible waste. The recommended ARF and RF values are 0.0005 and 1.0 (DOE 1994d). For the noncombustible waste, the ARF and RF values are 0.006 and 0.01 (DOE 1994d). Due to the penetration of the building by the aircraft-related missiles and/or due to external or internal explosion of fuel, the LPF is taken to be 1.0.

The general initial source term equation is quantified below for the two aircraft types that contribute to the crash frequency, as well as for both combustible and noncombustible waste forms:

Multiple-Engine Piston Aircraft:

Initial Combustible Source Term = MAR x DR x ARF x RF x LPF

= 8,772 x (0.132 x 0.35) x 0.0005 x 1 x 1

= 0.2 PE-Ci

Initial Noncombustible Source Term = MAR x DR x ARF x RF x LPF

= 8,772 x (0.132 x 0.65) x 0.006 x 0.01 x 1

= 0.05 PE-Ci

Multiple-Engine Piston Initial Source Term Total = Initial Combustible + Initial Noncombustible

= 0.2 + 0.05

= 0.25 PE-Ci

Small Military Aircraft:

Initial Combustible Source Term = MAR x DR x ARF x RF x LPF

= 8,772 x (0.574 x 0.35) x 0.0005 x 1 x 1

= 0.88 PE-Ci

Initial Noncombustible Source Term = MAR x DR x ARF x RF x LPF

= 8,772 x (0.574 x 0.65) x 0.006 x 0.01 x 1

= 0.20 PE-Ci

Air Taxi Aircraft Initial Source Term Total = Initial Combustible + Initial Noncombustible

= 0.88 + 0.20

= 1.08 PE-Ci

Following the initial source term release, resuspension releases are possible due to dispersal of material by the wind. For an aircraft crash, a 24-hour suspension release is reasonable due to the significant damage resulting from the aircraft crash and subsequent explosion and fire.

The general suspension source term equation is used. The DR is simply the fraction of the area burned because the ARR/hr and RF values are the same for both combustible and noncombustible waste. The ARF and RF values are selected from DOE Handbook 3010-94 and are based on the bounding values for packaged mixed waste. The recommended ARR and RF values are 4 x 10^{-5} per hour and 1.0 (DOE 1994d). Due to the penetration of the building by the aircraft-related missiles and/or due to external or internal explosion of fuel, the LPF is taken to be 1.0. It is assumed that temporary confinement cannot be erected or otherwise established for 24 hours to control suspension releases.

The suspension source term equation also must be quantified individually for each of the two crash frequency contributors:

Multiple-Engine Piston Aircraft:

Suspension Source Term = MAR x DR x ARR/hr x 24 hrs x RF x LPF

= 8,772 x 0.132 x 0.00004 x 24 x 1 x 1

= 1.1 PE-Ci

Small Military Aircraft:

Suspension Source Term = MAR x DR x ARR/hr x 24 hrs x RF x LPF

= 8,772 x 0.574 x 0.00004 x 24 x 1 x 1

= 4.8 PE-Ci

In order to specify a single source term for the RAMROD aircraft crash accident, the initial source terms and suspension source terms are frequency-weighted according to their contributions to the overall risk, as shown in Tables G.5.6.6–1 and G.5.6.6–2.

Based on these calculations, the source term for RAD–06 for the No Action Alternative is represented with an initial source term of 0.63 PE-Ci released in 30 minutes, and a suspension source term of 2.8 PE-Ci released over 24 hours.

There are no differences in source term across the alternatives because the No Action Alternative source terms are based on the RCRA-permitted capacity of the building.

Uncertainties and Sensitivities Affecting the Source Term for RAD–06

The source terms (initial and suspension) are maximum values, based on the RCRA-permitted capacity of the building. At any given time, there may be less TRU waste in the building than the permitted capacity. The average amount of TRU waste in combustible form may vary (an average value was used).

The suspension source term calculation extends for 24 hours. This may be very conservative in that it is likely that fire fighting and hazardous material (HAZMAT) response to the crash scene would be accompanied by extensive use of water and foam-based suppression systems. This application of suppressants would likely continue for some time to preclude flareup of the fire once it is extinguished, as well as to limit further spread of airborne plutonium contamination. Thus, the suspension source term may be very conservatively estimated for this scenario.

Consequences of RAD–06 for Facility Workers and the Public

Consequences for facility workers and the public are reported separately. An aircraft crash into the facility that destroys part of the facility is assumed to result in the death of all workers

TABLE G.5.6.6–1.—*Frequency Weighted Source Term Calculation for Initial Source Term*

AIRCRAFT TYPE	PERCENTAGE CONTRIBUTION TO AIRCRAFT CRASH FREQUENCY	INITIAL SOURCE TERM (PLUTONIUM-239 PE-Ci)	WEIGHTED INITIAL SOURCE TERM (PLUTONIUM-239 PE-Ci)
Multiple-Engine Piston	52.3%	0.25	0.13
Small Military	46.2%	1.08	0.50
TOTAL	98.5%		0.63

TABLE G.5.6.6–2.—*Frequency Weighted Source Term Calculation for Suspension Source Term*

AIRCRAFT TYPE	PERCENTAGE CONTRIBUTION TO AIRCRAFT CRASH FREQUENCY	SUSPENSION SOURCE TERM (PLUTONIUM-239 PE-Ci)	WEIGHTED SUSPENSION SOURCE TERM (PLUTONIUM-239 PE-Ci)
Multiple-Engine Piston	52.3%	1.1	0.58
Small Military	46.2%	4.8	2.22
TOTAL	98.5%		2.80

in the part destroyed. Workers elsewhere in the structure may be injured or killed due to flying debris or secondary effects from the fire (e.g., smoke inhalation). Workers in the building who are not directly affected by the crash and explosion or fire may be exposed to radiation as a result of plutonium inhalation. If the building collapses as a result of the impact of the aircraft, additional injuries or fatalities could result.

No acute fatalities are predicted to result from the postulated accident. The mean collective population dose is projected to total approximately 7,900 person-rem (TEDE), resulting in 4.2 excess LCFs. No ground contamination results or MEI doses are presented because the accident is incredible. Table G.5.6.6–3 summarizes the modeling results for RAD–06.

G.5.6.7 *RAD–07, TRU Waste Container Storage Area Fire at WCRR Facility*

General Scenario Description

The Waste Characterization, Reduction, and Repackaging (WCRR) Facility performs a variety of activities related to characterization, volume reduction, and repackaging, primarily for TRU waste. In order to support these activities, an outdoor Container Storage Area is provided just to the south of the WCRR Facility main building. Accident scenario RAD–07 involves a fire at the Container Storage Area, resulting in the release of plutonium from the TRU waste (which is contained in DOT Type A 55-gallon drums). The Container Storage Area has a RCRA Part B permitted capacity of 30,000 gallons of mixed waste, which is equivalent to 545, 55-gallon drums. WCRR Facility also has a RCRA Part B permitted capacity of 1,500 gallons of mixed waste (equivalent to 27, 55-gallon drums).

TABLE G.5.6.6–3.—*Summary Results for RAD–06*

ALTERNATIVE	ACCIDENT FREQUENCY	SOURCE TERM AND CONSEQUENCES
No Action	6.5×10^{-8}	Initial release of 0.63 PE-Ci, released in 30 minutes; Suspension source term of 2.8 PE-Ci, released over 24 hours; integrated population exposure of 7,900 person-rem and 4.2 excess LCFs.
Expanded Operations	6.5×10^{-8}	Same as No Action Alternative.
Reduced Operations	6.5×10^{-8}	Same as No Action Alternative.
Greener	6.5×10^{-8}	Same as No Action Alternative.

RAD–07 Release Mechanisms

The postulated RAD–07 accident scenario involves an airborne release of radioactive material due to a fire that develops at the outdoor container storage area. Potential accident initiators include: (1) truck fires, (2) forklift fires, (3) external fires (wild fires), (4) lightning strikes, and (5) aircraft accidents. Lightning may strike the Container Storage Area or pose an indirect hazard by initiating a wildfire. The Container Storage Area does not have lightning protection; however, a lightning strike would, at most, pose a localized hazard due to ignition of combustible waste. It would have a very limited opportunity to propagate with waste contained in metal drums and the low combustible loading of the storage array. Wild fires, initiated by lightning strikes or otherwise, do not pose a significant hazard considering the developed nature of the area (e.g., pavement), the low vegetation loading of the immediate surrounding area, and the time available to take mitigative actions. A forklift fire would be credible, but would be significantly bounded by the MAR for a truck fire accident.

Two truck fire scenarios could occur. The first is an accident involving a truck that causes a fuel leak and subsequent fire involving the Container Storage Area. This is judged not to be credible considering the low truck speeds involved in the confined yard area and the limited vehicle traffic, with the exception of forklift activity. The second involves a truck parked near the Container Storage Area that could experience a fuel system leak or fuel tank leak due to causes unrelated to a vehicle accident. Once a fuel leak occurs, ignition of the spilled fuel would lead to a fire that, if it is close enough to the Container Storage Area and if it is not suppressed, would envelope multiple waste containers. This scenario is retained for analysis.

While not required by the RCRA Part B permit, waste drums are currently stored in transportables for weather protection. The analysis takes no credit for the separation provided by the transportables because the RCRA Part B permit does not require their use. This accident was not evaluated in the WCRR Facility SAR (LANL 1995e).

No Action Alternative Frequency Analysis

The frequency (F_{FIRE}) of a truck fuel leak and subsequent fire accident can be estimated using the following equation:

$$F_{FIRE} = N_{SHIPMENTS} \times C_{LEAK} \times C_{PFIRE}$$

where:

$N_{SHIPMENTS}$ = Number of shipments to or from the Container Storage Area at TA–50–69 per year

C_{LEAK} = Conditional probability of fuel leak per shipment

C_{PFIRE} = Conditional probability of a fire given a fuel leak

The frequency of a fuel system leak or fuel tank leak and a resulting fire is assessed for the Container Storage Area at TA–50–69 based on methods and data described in section G.5.10, RAD–01. The per trip fuel leak rate is 1.3×10^{-3} per trip, with 24 shipments per year assumed for the purposes of analysis (2 shipments per month). Thus, the above equation can be quantified as follows:

$$F_{FIRE} = N_{SHIPMENTS} \times C_{LEAK} \times C_{PFIRE}$$

$$F_{FIRE} = 24 \times (1.3 \times 10^{-3}) \times (4.7 \times 10^{-3})$$

$$F_{FIRE} = 1.5 \times 10^{-4} \text{ per year}$$

In order to assure that the frequency of a fire due to forklift activity was dominated by the truck fire scenario, the frequency of a forklift fire was estimated. The frequency of a forklift fire ($F_{FLFTFIRE}$) leading to a release of TRU material at the Container Storage Area may be analyzed using the following equation:

$$F_{FLFTFIRE} = N_{FMOVE} \times N_{HOUR} \times F_{FUEL} \times C_{PING}$$

where:

N_{FMOVE} = Number of forklift movements per year

N_{HOUR} = Number of hours per forklift movement adjacent to Container Storage Area

F_{FUEL} = Frequency of a fuel tank rupture per hour

C_{PING} = Conditional probability of ignition given a fuel tank rupture

Forklift movements at TA–50–69 occur on an individual drum basis and on a palletized basis at the time of receipt and shipment. The WCRR Facility SAR (LANL 1995e) estimates 200 movements of palletized drums per year. Individual drum movements are not evaluated in the SAR. However, based on four drums per pallet, two palletized movements per set of four drums (for unloading and loading), and that individual drum movements would occur when waste drums are brought to and returned from the WCRR Facility, it is estimated that there are 800 ([200/2] x 2 x 4) individual drum movements per year.

The frequency of a forklift fuel tank rupture and a resulting fire is assessed based on methods and data contained in the TA–54, Area G Hazard Analysis (LANL 1995g), which references the evaluation of ignition probabilities given a tank rupture by the Reliability Analysis Center (RAC 1991). The frequency of a fuel tank rupture was assessed as 2.3×10^{-5} per hour in the TA–54 hazard analysis (LANL 1995g). For a nondiesel fuel (propane), the conditional probability of ignition given a rupture is assigned a value of 1×10^{-2}. It is conservatively assumed that each forklift movement lasts 0.5 hour. For individual drum movements, it is assumed the forklift movement time is equally divided at the Container Storage Area, in transit to the facility, and at the facility. For the palletized movements, it is assumed that the forklift time is equally spent immediately near the Container Storage Area and at the truck. Because of the small fuel capacity of the forklift as compared with the truck, it is assumed that any forklift incidents at the truck would not involve the Container Storage Area. Additionally, it is noted that forklift activities would be in the vicinity of the truck bed and, thus, would not involve the truck/tractor fuel tanks.

Thus, the above equation for forklift movements near the Container Storage Area can be quantified as follows:

$$F_{FLFTFIRE} = N_{FMOVE} \times N_{HOUR} \times F_{FUEL} \times C_{PING}$$

$$= [800 \text{ moves} \times (0.5/3 \text{ hr/move}) + 200 \text{ moves} \times (0.5/2 \text{ hr/move})] \times (2.3 \times 10^{-5} \text{ /hr}) \times (1 \times 10^{-2})$$

$$= 4.2 \times 10^{-5} \text{ per year}$$

The calculated frequency for a forklift fire involving the Container Storage Area is less than that for a truck fire. Additionally, the MAR for a postulated forklift fire would be much less than that for a truck fire. Consequently, truck fires dominate potential risks and forklift fire contributions are not considered further.

Expanded Operations Alternative Frequency Analysis

The Expanded Operations Alternative waste management practices and the low-level radioactive mixed waste (LLMW) generation rate will be comparable to the No Action Alternative. However, TRU waste volumes are expected to double (5,100 versus 2,500 cubic meters) from those in the No Action Alternative (LANL 1997c). On this basis, it is expected that waste throughput at WCRR Facility and the associated frequency of a potential truck fire at the Container Storage Area will be greater than in the No Action Alternative. Historically, WCRR Facility activities have primarily involved TRU waste characterization and volume reduction. Consequently, it is assumed that the change in throughput at WCRR Facility will be directly proportional to the change in TRU waste volume, resulting in 49 shipments per year (24 x 5,100/2,500).

With a revised number of truck shipments for the Expanded Operations Alternative, the frequency (F_{FIRE}) of a truck fuel leak and subsequent fire accident can be estimated as:

$$F_{FIRE} = N_{SHIPMENTS} \times C_{LEAK} \times C_{PFIRE}$$

$$F_{FIRE} = 49 \times (1.3 \times 10^{-3}) \times (4.7 \times 10^{-3})$$

$$F_{FIRE} = 3.0 \times 10^{-4} \text{ per year}$$

Reduced Operations Alternative Frequency Analysis

For the Reduced Operations Alternative, waste management practices and the LLMW waste generation rate will be comparable to the No Action Alternative. However, TRU waste volumes are expected to be almost 25 percent less (1,900 versus 2,500 cubic meters) than those for the No Action Alternative (LANL 1997c). On this basis, it is expected that waste throughput at WCRR Facility and the associated frequency of a potential truck fire at the Container Storage Area will be less than in the No Action Alternative. Historically, WCRR Facility activities have primarily involved TRU waste characterization and volume reduction. Consequently, it is assumed that the change in throughput at WCRR Facility will be directly proportional to the change in TRU waste volume, resulting in 18 shipments per year (24 x 1,900/2,500).

With a revised number of truck shipments for the Reduced Operations Alternative, the frequency (F_{FIRE}) of a truck fuel leak and subsequent fire accident can be estimated as:

$$F_{FIRE} = N_{SHIPMENTS} \times C_{LEAK} \times C_{PFIRE}$$

$$F_{FIRE} = 18 \times (1.3 \times 10^{-3}) \times (4.7 \times 10^{-3})$$

$$F_{FIRE} = 1.1 \times 10^{-4} \text{ per year}$$

Greener Alternative Frequency Analysis

For the Greener Alternative, waste management practices and waste generation rates for LLMW and TRU waste will be comparable to those for the No Action Alternative. On this basis, it is expected that waste throughput at WCRR Facility and the associated frequency of a potential truck fire at the Container Storage Area will be the same as in the No Action Alternative.

Uncertainties and Sensitivities Affecting the Frequency of RAD–07

Insofar as the fire modeling is concerned, the uncertainties affecting the frequency of RAD–07 are identical to those affecting CHEM–02. The frequency results are also sensitive to the assumed number of shipments per year for the Container Storage Area.

Source Term Calculations

The initial source term equation is used for this case. The MAR for the postulated accident is limited to the Container Storage Area waste inventory immediately involved in the truck fuel pool fire. Propagation of the fire to the entire inventory is not expected, as discussed in section G.5.16.1. The MAR is estimated for a 100-gallon (379-liter) fuel spill, yielding a burn area of 500 square feet (46 square meters). This is based on a burn area relationship of 250 square feet for 50 gallons of fuel (23 square meters for 189 liters of fuel) (RFETS 1994). Assuming that half the burn area is off center from the Container Storage Area and that half the remaining area involves waste (allows for aisle/access space), approximately 62 drums (stacked two high) would be involved (125 square feet x 2 drums/4 square feet).

Potential waste forms present include solidified liquids (aggregate); surface contaminated, packaged combustible solids; and surface contaminated, noncombustible solids. The bounding ARF and RF products for these three waste forms in a thermal stress environment (fire) are 6×10^{-5}, 5×10^{-4}, and 6×10^{-5}, respectively (DOE 1994d). Consequently, it can be concluded that releases will be dominated by combustible waste and the analysis will be limited to this waste form. It is conservatively assumed that the combustible waste fraction at the Container Storage Area is the same as that for the TRU waste inventory at Area G. The Container Storage Area combustible waste fraction is likely to be much lower due to the facility's primary mission of size reduction of metal objects, such as gloveboxes; however, combustible waste forms would be expected to be present due to characterization activities. Additionally, it is conservatively assumed that 35 percent of the radiological inventory is present in combustible waste forms. Thus, for the MAR (62 drums), the DR is set equal to the fraction of combustible material (0.35). The Container Storage Area is located outdoors; consequently, any postulated accident involving a release to the environment would have an LPF of 1.0.

Proposed administrative limits for the radionuclide content of each individual waste container are presented in Table 9-2 of the WCRR Facility SAR (LANL 1995e) and are based on DOE Standard 1027-92 (DOE 1992) Hazard Category 3 threshold limits or a fissile gram equivalent limit based on the WIPP WAC. Currently, the average TRU radioactive material content per waste container is 8.9 PE-Ci (LANL 1995f). Less than 1 percent of all TRU waste containers in the existing Area G inventory exceed 75 PE-Ci in radioactive material content (LANL 1995f). The predominant TRU waste generated at LANL is weapons-grade plutonium (MT52). The LANL fissile gram equivalent limit for this material type is 25 PE-Ci per drum (LANL 1995f). Revision 5 of the WIPP WAC limits the maximum plutonium-239 equivalent activity for untreated, contact-handled TRU waste to be received by the facility to 80 PE-Ci per drum. Considering that the postulated accident scenario involves multiple drums (62); that the drums represent a small fraction of the total TRU waste inventory managed at LANL, and their radioactive content could be skewed to the high end (depending on the waste generator source); and the TRU limits described above; it is conservatively assumed that one drum contains the WIPP WAC limit for untreated waste of 80 PE-Ci and the other 61 drums involved in the fire have an average TRU content of 25 PE-Ci.

With the above information, the initial source term equation can be quantified as follows:

$$\text{Initial Source Term} = \text{MAR} \times \text{DR} \times \text{ARF} \times \text{RF} \times \text{LPF}$$

$$= ([61 \times 25 \text{ PE-Ci}] + 80 \text{ PE-Ci}) \times 0.35 \times (5 \times 10^{-4}) \times 1 \times 1$$

$$= 0.28 \text{ PE-Ci}$$

The suspension source term calculation is performed using the general equation. The suspension MAR equals the initial MAR, minus the initial source term. The suspension DR and LPF have the same values (1.0) as in the initial source term calculation. The ARR and RF are assigned values of 4×10^{-5} and 1.0, respectively, based on bounding resuspension factors for a homogeneous bed of powder exposed to ambient conditions (DOE 1994d). Thus, the suspension source term can be quantified as:

$$\text{Suspension Source Term} = \text{MAR} \times \text{DR} \times \text{ARR} \times 24 \text{ hrs} \times \text{RF} \times \text{LPF}$$

$$= (1{,}550 - 0.28 \text{ PE-Ci}) \times 0.35 \times (4 \times 10^{-5}) \times 24 \text{ hrs} \times 1 \times 1$$

$$= 0.52 \text{ PE-Ci}$$

The suspension source term is highly conservative, considering that fire protection actions (e.g., foam, water spray) and contamination control measures would likely limit airborne releases significantly.

No variation by alternative is projected because waste management practices are expected to be comparable (LANL 1997c), with the MAR and postulated accident conditions the same.

Uncertainties and Sensitivities Affecting the Source Term for RAD–07

A significant uncertainty for this postulated accident is quantification of the MAR in terms of the number of drums involved in the fire and their associated radioactive material content. Accepted methodologies and reasonably conservative radiological estimates have been made to provide an upper estimate of the source term.

Consequences of RAD–07 for Facility Workers and the Public

Typically, five facility workers are associated with TA–50–69 operations and would be at risk for exposure to airborne radioactive material. The postulated accident would not result in an immediate release, providing time for personnel to vacate the immediate area. Personnel in the facility may not have time to vacate before a release occurs; however, CAM alarms and the availability of personal protective equipment could serve to mitigate potential exposures.

No acute fatalities are predicted to result from the postulated accident. The mean collective population dose is projected to total 1,300 person-rem (TEDE), resulting in 0.69 excess LCFs. Mean projected doses for MEIs (and their associated locations) and ground contamination levels are presented in Tables G.5.6.7–2 and G.5.6.7–3, respectively. Table G.5.6.7–1 summarizes the modeling results for RAD–07.

G.5.6.8 *RAD–08, Aircraft Crash and Plutonium Release from TA–54 TWISP Storage Domes*

General Scenario Description

Accident Scenario RAD–08 involves the crash of an aircraft, accompanied by explosion and/or fire, at the TRU waste management area of TA–54, Area G. The largest target, which dominates the aircraft crash frequency results and also has a very large potential MAR, consists of the storage domes for the Transuranic Waste Inspectable Storage Project (TWISP).

TABLE G.5.6.7–1.—*Summary Results for Scenario RAD–07*

ALTERNATIVE	ACCIDENT FREQUENCY	SOURCE TERM AND CONSEQUENCES
No Action	1.5×10^{-4}	Initial release of 0.28 PE-Ci; Suspension release of 0.52 PE-Ci; integrated population exposure of 1,300 person-rem, 0.69 excess LCFs.
Expanded Operations	3.0×10^{-4}	Same as No Action Alternative.
Reduced Operations	1.1×10^{-4}	Same as No Action Alternative.
Greener	1.5×10^{-4}	Same as No Action Alternative.

TABLE G.5.6.7–2.—*Predicted Mean Doses to MEIs for Scenario RAD–07*

MAXIMUM EXPOSED INDIVIDUAL (MEI) DOSE (REM, TEDE)	
MEI LOCATION	DOSE
Closest public access: Pajarito Road (100 m)	7.4×10^{1}
Special population distance: San Ildefonso Pueblo boundary (500 m)	3.5×10^{0}
Closest public residence: Royal Crest Trailer Park (1,200 m)	7.4×10^{-1}
Closest special population distance: Ashley Pond (2,100 m)	2.6×10^{-1}
Special population distance: San Ildefonso Pueblo (13,600 m)	1.4×10^{-2}

TABLE G.5.6.7–3.—*Predicted Mean Ground Contamination Levels for Scenario RAD–07*

RADIAL DISTANCE	PLUTONIUM-239 GROUND CONCENTRATION (BQ/m^2)
0.0 to 1.0 km	1.7×10^{4}
1.0 to 2.0 km	1.7×10^{3}
2.0 to 3.0 km	6.7×10^{2}
3.0 to 4.0 km	3.8×10^{2}
4.0 to 8.0 km	1.8×10^{2}
8.0 to 12.0 km	9.3×10^{1}
12.0 to 20.0 km	5.5×10^{1}
20.0 to 30.0 km	2.9×10^{1}
30.0 to 40.0 km	1.6×10^{0}
40.0 to 60.0 km	9.3×10^{0}
60.0 to 80.0 km	4.9×10^{0}

BQ/m^2 = Becquerel per square meter

TRU waste is stored in aluminum arch-frame supported, membrane-covered domes that rest on asphalt pads. Four domes are in use as storage for TRU waste generated since the early part of 1991, designated as TA–54–48, TA–54–153, TA–54–224, and TA–54–283. The storage capacity is 11,000 drums, and there were 3,600 drums in storage as of the end of 1995.

Previously, from 1979 to 1991, TRU waste was stored in retrievable arrays under several feet of earth on three pads (Pads 1, 2, and 4). This retrievable TRU waste is being removed from this configuration and temporarily placed into storage dome structures. The retrieved waste is characterized, repackaged, and certified to WIPP WAC. (All of the retrievable TRU waste is planned to be shipped to WIPP after 1998.) Once the retrieved waste is characterized, repackaged, and WIPP WAC-certified, it will be stored in one of six dome structures, designated as TA–54–229, TA–54–230, TA–54–231, and TA–54–232 (plus two domes yet to be constructed). The four domes are located adjacent to one another at the far eastern extent of the TA–54 operating area; the other two domes will be located at a distance from the four TWISP domes so as to constitute a separate target area, the contribution to risk of which will be bounded by the four existing TWISP storage domes.

The characteristics of the TRU waste to be retrieved from Pads 1, 2, and 4 are generally known as detailed in Table G.5.6.8–1 (LANL 1996n). There are a total of 16,641 drums: 5,487 drums of combustible waste containing an average of 4.34 PE-Ci of plutonium-239 each, and 11,154 drums of noncombustible waste containing an average of 4.11 PE-Ci of plutonium-239 each. There are also 187 fiberglass-reinforced plastic-coated plywood (FRP) crates: 33 FRP crates of combustible waste containing an average of 12.5 PE-Ci of plutonium-239 each, and 154 FRP crates of noncombustible waste containing an average of 8.6 PE-Ci of plutonium-239 each. The total inventories of the three pads are: 7,812 PE-Ci of plutonium-239 for Pad 1; 24,052 PE-Ci of plutonium-239 for Pad 2; and 39,502 PE-Ci of plutonium-239 for Pad 4. In total, the FRP crates represent 1,736 PE-Ci of plutonium-239, or about 2.4 percent of the total TRU waste inventory.

TABLE G.5.6.8–1.—*Characterization of TRU Waste in Pads 1, 2, and 4 at TA–54 Area G*

TRU PAD #1, USED FROM 5/29/79 TO 12/29/81
4,816 Drums
1,276 drums of combustible waste containing 2,240 PE-Ci of plutonium-239
3,540 drums of noncombustible waste containing 4,400 PE-Ci of plutonium-239
88 FRP Crates
8 FRP crates of combustible waste containing 2.03 PE-Ci of plutonium-239
80 FRP crates of noncombustible waste containing 1,170 PE-Ci of plutonium-239
TRU PAD #2, USED FROM 12/8/81 TO 8/20/85
7,280 Drums
2,475 drums of combustible waste containing 6,890 PE-Ci of plutonium-239
4,805 drums of noncombustible waste containing 17,100 PE-Ci of plutonium-239
48 FRP Crates
22 crates of combustible waste containing 1.47 PE-Ci of plutonium-239
26 crates of noncombustible waste containing 60.3 PE-Ci of plutonium-239
TRU PAD #4, USED FROM 3/18/85 TO 1/3/91
4,545 Drums
1,736 drums of combustible waste containing 14,700 PE-Ci of plutonium-239
2,809 drums of noncombustible waste containing 24,300 PE-Ci of plutonium-239
51 FRP Crates
3 FRP crates of combustible waste containing 410 PE-Ci of plutonium-239
48 FRP crates of noncombustible waste containing 91.9 PE-Ci of plutonium-239

No detailed apportionment of the TRU waste recovered from Pads 1, 2, and 4 among the four domes (TA–54–229, TA–54–230, TA–54–231, and TA–54–232) have been identified. For the purposes of this analysis, it is assumed that the TWISP TRU inventory, in terms of PE-Ci, is split evenly among the six domes. Thus, each dome is assumed to contain 4,041 PE-Ci of Plutonium-239 as combustible TRU waste and 7,854 PE-Ci of noncombustible TRU waste.

At the average content values identified above, this would represent about 931 drums of combustible TRU waste and 1,911 drums of noncombustible TRU waste. (This is a slight over-estimate, but considered to be reasonable considering possible repackaging.)

In the storage domes, TRU waste drums are palletized (four drums to a pallet) and stored in inspectable arrays. The arrays consist of palletized drums stacked three high, separated by a minimum aisle space of 26 inches (66 centimeters). FRP crates and standard waste boxes (SWBs) are also stored in these structures. FRP crates and SWBs are stored in rows and stacked one to three boxes high (LANL 1995f). LANL is in the process of exchanging plywood pallets for metal pallets to reduce fire hazards in the TRU waste domes.

Fire-fighting water for Area G is provided by a 10-inch main from a water distribution system supplied by two water tanks near TA–54. The primary tank is a gravity feed with a 1.5 million gallon domestic booster pump (booster station 2). The secondary tank is a pressure feed with a 1.5 million gallon domestic booster pump (booster station 1). Water mains are designed to provide 1,170 gallons per minute at the fire hydrants with a residual pressure of 20 psi (LANL 1996n). Fire-fighting equipment can arrive at TWISP operations in 8 to 12 minutes. The initial response is two pumpers capable of dispensing 1,250 gallons per minute with a 500-gallon onboard storage capacity each, one light rescue vehicle, and one staff vehicle. An additional pumper is available on the second alarm (LANL 1996n).

In addition to fire-fighting response, LANL ESH-10 maintains a HAZMAT team at TA–64. The HAZMAT team would respond to an accident such as an aircraft crash at TA–54 Area G.

The TA–54 Area G SAR did not evaluate aircraft crash accidents. Aircraft crash at a TRU waste dome was identified in the TA–54 Area G Hazard Analysis with a frequency assigned as below 1 x 10^{-6} per year based on expert judgment (LANL 1995g).

A separate LANL study evaluated aircraft crash frequency at TA–54 by calculating the crash frequency for the largest building at the site, which is one of the TWISP fabric domes at 320 feet (98 meters) long, 246 feet (75 meters) wide, and 38 feet (12 meters) high. The study calculated the aircraft crash at 1.02 x 10^{-8} per year (LANL 1996c).

No Action Alternative Frequency Analysis

The air space above LANL is restricted up to 14,000 feet, designated as Restricted Airspace R-5101 (LANL 1996c). However, DOE Standard 3014-96 states that once an in-flight mishap does occur, with eventual loss of control, there is nothing to prevent a disabled aircraft from crashing into any location, even within a restricted airspace area (DOE 1996c).

The TRU waste storage domes at TA–54 Area G were reviewed. As a result of their locations, TA–54–153 and TA–54–283 are essentially a single target (they are separated by less than 100 feet [31 meters]); TA–54–283 is a temporary structure.

TA–54–224 represents another target (separated from TA–54–283 and TA–54–153 by over 100 feet (31 meters). TA–54–48 is still another stand-alone target, being more than 100 feet (31 meters) from the TA–54–229 through

TA–54–232 group of domes. TA–54–229 through TA–54–232 represent a single target as they are adjacent to one another separated by less than 50 feet (15 meters) between the domes.

The TWISP retrieval dome, as well as the two temporary domes used to house TWISP waste after retrieval but before repackaging (TA–54–224 and TA–54–283), are all temporary structures. The only permanent structures will be the two existing domes used to store TRU waste from ongoing operations (TA–54–48 and TA–54–153), as well as the four TWISP storage domes (TA–54–229 through TA–54–232). Because TA–54–283 is a temporary structure, essentially there are two single dome targets (TA–54–48 and TA–54–153) and the four-dome target (TA–54–229 through TA–54–232). The single dome targets will represent a small fraction of the total effective aircraft target area for TA–54. Accordingly, aircraft crash analytical efforts were focused on the four-dome TWISP storage dome target.

Based on the TWISP SAR, the four TWISP domes were analyzed as one target with dimensions of 414 feet (126 meters) long, 286 feet (87 meters) wide, and 38 feet (12 meters) high. Skid distance is limited due to the Finger Mesa location, but has been established at 50 feet (15 meters) for conservatism. Based on physical inspection, this is reasonable for all directions except north, for which a longer skid distance can be justified. Considering the configuration of the mesa, a 50-foot (15 meter) skid distance is judged to adequately represent the site.

The estimated perforation/fire frequency for the TWISP domes is 4.3×10^{-6} per year. The crash frequency is dominated by single-engine piston aircraft, multiple-engine piston aircraft, and small military aircraft (the air taxi frequency contribution is conservatively binned with small military in this case), representing 98.2 percent of the total perforation/fire frequency.

Expanded Operations, Reduced Operations, and Greener Alternatives Frequency Analysis

Aircraft crash rates in the vicinity of LANL are not significantly associated with the level of activity at LANL. Accordingly, the frequency of aircraft crash does not vary by alternative.

Uncertainties and Sensitivities Affecting the Frequency of RAD–08

There is a large amount of data required to perform the DOE Standard 3014-96 calculations. In addition, the standard itself requires the use of numerous equations that are recognized to be approximations. Perhaps the most important uncertainty is the assumption (embedded in the standard) that a skidding aircraft will impact a facility with the same velocity it had when it began the skid. This results in a conservative impact velocity because no credit is taken for drag, friction, impact with objects between the impact point and the facility, and so on.

Another conservatism for the TA–54 Area G analysis is the assumption of a 38-foot (12-meter) height for the target. This is the actual height of the membrane domes, but these structures would not offer much resistance to aircraft. Aircraft could in principle strike the dome itself and pass through without impacting the TRU waste stored inside (at least this would be possible with aircraft approaching from the east or west).

As a sensitivity calculation, the height was lowered to 12 feet (4 meters), representing two drum heights. The resulting frequency of perforation/fire crashes was 2.8×10^{-6} per year. The overall reduction in impact frequency for modeling the domes as 12 feet (4 meters) high instead of 38 feet (12 meters) high is less than a factor of two. It is concluded that the impact frequency results are not strongly sensitive to this parameter.

Source Term Calculations

Fires were evaluated for their source term contribution. Three aircraft types account for about 98.2 percent of the total aircraft crash frequency at the TWISP storage domes: (1) single-engine piston aircraft; (2) multiple-engine piston aircraft; and (3) small military aircraft. In order to evaluate the fire and explosion potential of these aircraft, the characteristics of the aircraft in these classes as identified in the supporting documentation for DOE Standard 3014-96 were used to select the bounding fuel load (LLNL 1996). The aircraft selected for these classes are: (1) the Piper Turbo line, with a fuel load of 128 gallons (486 liters), for the single-engine piston aircraft; (2) the Cessna Titan line, with a fuel load of 413 gallons (1,564 liters), for the multiple-engine piston aircraft; and (3) the F-16C, with a fuel load of 1,801 gallons (6,819 liters) for the small military aircraft (LLNL 1996). (The F-16 is typical of local military operations out of Kirtland Air Force Base in Albuquerque, for example.)

In order to quantify the burn area resulting from a spill of aircraft fuel and its subsequent combustion, guidance from the Rocky Flats Risk Assessment Guide was followed that provides an estimate of a 250 square-foot (23 square-meter) burn area per 50 gallons (189 liters) of fuel burned (RFETS 1994). Burn areas were calculated as follows for the three significant classes of aircraft:

$$A_{BURN} = (F_{LOAD}/50) \times 250 \text{ ft}^2$$

where:

A_{BURN} = Burn area in square feet

F_{LOAD} = Aircraft fuel load in gallons

The estimated burn area for each of the three significant aircraft types can now be calculated:

Single-Engine Piston Aircraft:

$$A_{BURN} = (F_{LOAD}/50) \times 250 \text{ ft}^2$$

$$A_{BURN} = (128/50) \times 250 \text{ ft}^2$$

$$A_{BURN} = 640 \text{ ft}^2$$

Multiple-Engine Piston Aircraft:

$$A_{BURN} = (F_{LOAD}/50) \times 250 \text{ ft}^2$$

$$A_{BURN} = (413/50) \times 250 \text{ ft}^2$$

$$A_{BURN} = 2{,}065 \text{ ft}^2$$

Small Military Aircraft:

$$A_{BURN} = (F_{LOAD}/50) \times 250 \text{ ft}^2$$

$$A_{BURN} = (1801/50) \times 250 \text{ ft}^2$$

$$A_{BURN} = 9{,}005 \text{ ft}^2$$

The area of one of the TWISP storage domes is 16,000 square feet (1,486 square meters). The burn areas identified above represent the following percentages of a single storage dome:

- Single-Engine Piston Aircraft = 4.0 percent
- Multiple-Engine Piston Aircraft = 12.9 percent
- Small Military Aircraft = 56.3 percent

As discussed above, each of the four TWISP storage domes is assumed to contain 4,041 PE-Ci of plutonium-239 as combustible TRU waste and 7,854 PE-Ci of noncombustible TRU waste. The source term contribution will be assumed to be "smeared" evenly across the floor area of the dome (16,000 square feet [1,486 square meters]); calculations will have to be performed separately for combustible and noncombustible fractions because the ARF and RF values are very different.

The DOE Handbook 3010-94 initial source term equation is used, and must be quantified separately for each type of aircraft contributing significantly to the crash frequency due to the difference in the impacted area of the facility; it is also quantified separately for combustible and noncombustible waste forms. Due to the random nature of aircraft crashes, no specific directionality is associated with the crashes. The damage ratio will be expressed as the percentage of the facility floor area burned in a fire (which will be assumed to equate to the fraction of the inventory affected by fire).

It is recognized that some crashes could result in a fire without affecting MAR; whereas, other crashes could burn a quantity of waste that is in excess of the fraction the floor area affected by the burn. However, the approach adopted above is believed to yield a reasonable result that is considered to be representative of the average that would result from a large number of crashes.

The ARF and RF values are selected from DOE Handbook 3010-94 and are based on the bounding values for packaged mixed waste. The recommended ARF and RF values for combustible waste are 0.0005 and 1.0 (DOE 1994d). The recommended ARF and RF values for noncombustible waste are 0.006 and 0.01 (DOE 1994d). The LPF is taken to be 1 because the TRU waste fabric domes do not represent a confinement structure and because the fabric membranes are assumed to be penetrated by aircraft or aircraft missiles, or breached due to extreme fire conditions.

The general initial source term equation is quantified below for the three aircraft types that contribute to the crash frequency:

Single-Engine Piston Aircraft:

Initial Combustible Source Term = MAR x DR x ARF x RF x LPF

= 4,041 x 0.04 x 0.0005 x 1 x 1

= 0.08E-Ci

Initial Noncombustible Source Term = MAR x DR x ARF x RF x LPF

= 7,854 x 0.04 x 0.006 x 0.01 x 1

= 0.02 PE-Ci

Total Initial Source Term = 0.08 + 0.02 = 0.10 PE-Ci

Multiple-Engine Piston Aircraft:

Initial Combustible Source Term = MAR x DR x ARF x RF x LPF

= 4,041 x 0.129 x 0.0005 x 1 x 1

= 0.26 PE-Ci

Initial Noncombustible Source Term = MAR x DR x ARF x RF x LPF

= 7,854 x 0.129 x 0.006 x 0.01 x 1

= 0.06 PE-Ci

Total Initial Source Term = 0.26 + 0.06 = 0.32 PE-Ci

Small Military Aircraft:

Initial Combustible Source Term = MAR x DR x ARF x RF x LPF

= 4,041 x 0.563 x 0.0005 x 1 x 1

= 1.14 PE-Ci

Initial Noncombustible Source Term = MAR x DR x ARF x RF x LPF

= 7,854 x 0.563 x 0.006 x 0.01 x 1

= 0.27 PE-Ci

Total Initial Source Term = 1.14 + 0.27 = 1.41 PE-Ci

Following the initial source term release, resuspension releases are possible due to dispersal of material by the wind. For an aircraft crash, a 24-hour suspension release is considered to be reasonable due to the significant damage resulting from the aircraft crash and subsequent explosion and fire. The general suspension source term equation is used to calculate the suspension source term. The DR is defined in the same manner as with the initial source term. The ARF and RF values are selected from DOE Handbook 3010-94 and are based on the bounding values for packaged mixed waste. The recommended ARR and RF values are 4 x 10^{-5} per hour and 1.0 (DOE 1994d). Due to the penetration of the building by the aircraft-related missiles and/or due to external or internal explosion of fuel, the LPF is taken to be 1.0. This is assumed to be applicable because it is considered unlikely that a temporary structure would be erected as soon as 24 hours to mitigate releases.

The suspension source term equation also must be quantified individually for each of the three crash frequency contributors (quantification is based on the total PE-Ci content because the ARR and RF values are the same regardless of whether the source MAR is combustible or not):

Single-Engine Piston Aircraft:

Suspension Source Term = MAR x DR x ARR/hr x 24 hrs x RF x LPF

= 11,895 x 0.04 x 0.00004 x 24 x 1 x 1

= 0.46 PE-Ci

Multiple-Engine Piston Aircraft:

Suspension Source Term = MAR x DR x ARR/hr x 24 hrs x RF x LPF

= 11,895 x 0.129 x 0.00004 x 24 x 1 x 1

= 1.47 PE-Ci

Small Military Aircraft:

Suspension Source Term = MAR x DR x ARR/hr x 24 hrs x RF x LPF

= 11,895 x 0.563 x 0.00004 x 24 x 1 x 1

= 6.43 PE-Ci

In order to specify a single source term for the TA–54 Area G aircraft crash accident, the initial source terms and suspension source terms are frequency-weighted below according to their contributions to the overall risk, as shown in Tables G.5.6.8–2 and G.5.6.8–3.

TABLE G.5.6.8–2.—*Frequency Weighted Source Term Calculation for Initial Source Term*

AIRCRAFT TYPE	PERCENTAGE CONTRIBUTION TO AIRCRAFT CRASH FREQUENCY	INITIAL SOURCE TERM (PLUTONIUM-239 PE-Ci)	WEIGHTED INITIAL SOURCE TERM (PLUTONIUM-239 PE-Ci)
Single-Engine Piston	0.884	0.10	0.088
Multiple-Engine Piston	0.060	0.32	0.019
Small Military	0.037	1.41	0.052
TOTAL	0.981		0.16

TABLE G.5.6.8–3.—*Frequency Weighted Source Term Calculation for Suspension Source Term*

AIRCRAFT TYPE	PERCENTAGE CONTRIBUTION TO AIRCRAFT CRASH FREQUENCY	SUSPENSION SOURCE TERM (PLUTONIUM-239 PE-Ci)	WEIGHTED SUSPENSION SOURCE TERM (PLUTONIUM-239 PE-Ci)
Single-Engine Piston	0.884	0.46	0.41
Multiple-Engine Piston	0.060	1.47	0.09
Small Military	0.037	6.43	0.24
TOTAL	0.981		0.74

Based on these calculations the source term for RAD–08 for the No Action Alternative will be represented with an initial source term of 0.16 PE-Ci released in 30 minutes, and a suspension source term of 0.74 PE-Ci released over 24 hours. There are no differences in source term across the alternatives (because the No Action Alternative source terms are based on the average maximum quantity of TRU waste in the four TWISP storage domes). The TWISP source term is identical across the alternatives.

Uncertainties and Sensitivities Affecting the Source Term for RAD–08

The source terms (initial and suspension) are the average maximum values expected for the TWISP storage domes once they are fully loaded. Of course, it is possible that an aircraft crash would occur in a dome that is not fully loaded (or even empty, depending on timing). Clearly, the values calculated above are bounding, assuming the average maximum quantities are correct.

The number of TWISP storage domes occupied with TRU waste will depend on the processing rate during TWISP recovery and repackaging and also on the WIPP shipment rate. Neither of these rates is known with precision, particularly the latter. Thus, a bounding calculation was performed.

The suspension source term calculation extends for 24 hours. This may be very conservative in that it is likely that fire fighting and HAZMAT response to the crash scene would be accompanied by extensive use of water and foam-based suppression systems. This application of suppressants would likely continue for some time to preclude flareup of the fire once it is extinguished, as well as to limit further spread of plutonium contamination.

Consequences of RAD–08 for Facility Workers and the Public

The consequences of RAD–08 for facility workers and the public are discussed separately. Typically, only a small number of facility workers would be expected to be present at the TWISP domes, and would be at risk for possible exposure to airborne radioactive material as well as exposure to the dynamics of the aircraft crash. An aircraft crash into the dome that destroys part of the facility is assumed to result in the death of all workers in the part that is destroyed. Workers elsewhere in the structure may be injured or killed due to flying debris or secondary effects from the fire (e.g., smoke inhalation). Workers in the dome who are not directly affected by the crash and explosion or fire may be exposed to radiation as a result of plutonium inhalation. If the dome collapses as a result of the impact of the aircraft (which is to be expected), additional injuries or fatalities could result.

No acute fatalities are predicted to result from the postulated accident. The mean collective population dose is projected to total 400 person-rem (TEDE), resulting in 0.2 excess LCFs. Mean projected doses for MEIs (and their associated locations) and ground contamination levels are presented in Tables G.5.6.8–5 and G.5.6.8–6, respectively. Table G.5.6.8–4 summarizes the modeling results for RAD–08.

G.5.6.9 *RAD–09, Plutonium Release from TRU Waste Drum Failure or Puncture*

General Scenario Description

A contact-handled TRU waste drum failure/ puncture is postulated to occur during drum handling operations (all subsequent discussions refer to the waste as TRU waste). Either a complete or a partial drum spill may occur. A complete spill of drum contents is more likely to occur during retrieval of TRU waste from Pads 1, 2, and 4 at TA–54, Area G (considering the potential for degraded drums and the number of drums to be retrieved, 16,641). A partial spill of drum contents would result from drum puncture accidents or from the majority of drop related accidents. This scenario assumes a complete spill occurs to represent failure of a degraded drum and to conservatively bound an individual or multiple drum puncture accident. A large majority of drum handling operations occur outdoors or within structures that do not have HEPA filtration. Consequently, the accident scenario postulates that the incident occurs outdoors. The drum failure/puncture scenario could occur at multiple facilities at TA–3, TA–16, TA–50, TA–54, or TA–55. The accident is postulated to occur at TA–54, Area G because the large majority of TRU waste drum handlings occur there.

Drum handling operations are primarily conducted with forklifts/lift trucks. Exceptions include the use of drum dollies for movements within facilities or dock areas, drum lift fixtures for glovebox entry/egress, manual methods (such as individual drum retrieval activities at Pads 1, 2, and 4), and crane/hoist activities (such as WCRR Facility enclosure movements or RANT transportation bay loading activities). Drum handling may be conducted on an individual drum basis, on a palletized basis (four drums banded together), or on a 7-pack basis (seven drums banded together by metal banding or plastic stretch wrap for shipment to WIPP in a TRUPACT-II container). Drum drop tests at Hanford (WHC 1995) have demonstrated that dropping a pallet of four banded drums results in damage to a single drum. Consequently, the MAR (one drum) for this postulated accident scenario would be representative of an accident involving the handling of multiple drums.

Because waste management activities involve the movement of a large number of TRU waste containers, with the large majority having a low radioactive material content, risks associated with a drum failure/puncture will be evaluated for both an average and a high radioactive content drum.

Note that this accident scenario does not include TRU waste drum handling operations associated with possible retrieval of buried TRU waste located on Pads 9 and 29 and in Trenches A, B, C, and D. Possible retrieval of this waste was mentioned briefly as being conducted during the 10-year period covered by the SWEIS in the draft November 1996 Waste Management Strategies document issued by LANL (LANL 1996o), but insufficient specific information was available upon which to base a quantification of possible impacts.

A similar accident scenario is analyzed in the Safety Analysis Report for TA–54, Area G (LANL 1995f), with the exception that it assumes that intact drums are involved in the accident. The postulated accident scenario evaluated for the SWEIS is intended to cover potential accidents involving retrieval of degraded drums from earthen-covered storage

TABLE G.5.6.8–4.—*Summary of Results for Scenario RAD–08*

ALTERNATIVE	ACCIDENT FREQUENCY	SOURCE TERM AND CONSEQUENCES
No Action	4.3×10^{-6}	Initial source term of 0.16 PE-Ci released in 30 minutes; suspension source term of 0.74 PE-Ci, released over 24 hours; integrated population exposure of 400 person-rem, 0.2 excess LCFs.
Expanded Operations	4.3×10^{-6}	Same as No Action Alternative.
Reduced Operations	4.3×10^{-6}	Same as No Action Alternative.
Greener	4.3×10^{-6}	Same as No Action Alternative.

TABLE G.5.6.8–5.—*Predicted Mean Doses to MEIs for Scenario RAD–08*

MAXIMUM EXPOSED INDIVIDUAL (MEI) DOSE (REM, TEDE)	
MEI LOCATION	**DOSE**
Closest public access from TA–54–229: Pajarito Road (210 m)[a]	2.2×10^{1}
Closest site boundary from Pads 1, 2 and 3 White Rock (245 m) (see note) (TWISP SAR; TA–54 Area G SAR)	2.2×10^{1}
Special population distance from TA–54–229: San Ildefonso boundary (500 m)	7.2×10^{0}
Closest White Rock residence from TA–54–229 (1,500 m)	1.1×10^{0}
Closest population center from Pads 1, 2 and 3: White Rock (1,680 m) (TWISP SAR; TA–54 Area G SAR)	9.6×10^{-1}
Special population distance from TA–54–229: Piñon Elementary School/Park (2100 m)	6.6×10^{-1}
Special population distance from TA–54–229: San Ildefonso Pueblo (14,300 m)	2.5×10^{-2}

[a] Estimated using radial distance of 230 m.

TABLE G.5.6.8–6.—*Predicted Mean Ground Contamination Levels for Scenario RAD–08*

RADIAL DISTANCE	PLUTONIUM-239 GROUND CONCENTRATION (BQ/m^2)
0.0 to 1.0 km	3.9×10^4
1.0 to 2.0 km	5.1×10^3
2.0 to 3.0 km	2.1×10^3
3.0 to 4.0 km	1.2×10^3
4.0 to 8.0 km	4.8×10^2
8.0 to 12.0 km	1.9×10^2
12.0 to 20.0 km	6.6×10^1
20.0 to 30.0 km	2.8×10^1
30.0 to 40.0 km	1.5×10^1
40.0 to 60.0 km	7.2×10^0
60.0 to 80.0 km	3.5×10^0

BQ/m^2 = Becquerel per square meter

at Pads 1, 2, and 4. The SAR accident scenario results from forklift handling of a waste container. The accident frequency in the SAR is based on 5,000 waste container handling events per year at Area G, a waste handling accident frequency of 1×10^{-5} per container handling event, and a conditional probability of 1×10^{-2} of involving a maximum drum (1,000 PE-Ci). (The WIPP WAC previously allowed up to 1,000 PE-Ci per waste container.)

Selected parameter values that were used for this source term analysis were: (1) MAR—bounding value of 1,000 PE-Ci (previous WIPP WAC limit); (2) damage ratio—0.1, based on engineering judgement and cited drum drop test results for DOT Type A containers; (3) airborne release fraction—0.0001, bounding value for solid contaminated material from an early draft of DOE Handbook 3010-94; (4) respirable fraction—0.05, based on a draft of DOE Handbook 3010-94; and (5) leakpath factor—1.0 (bounding).

The Final Safety Analysis Report (FSAR) for the Retrieval for Transuranic Waste from Pads 1, 2, and 4 at TA–54, Area G evaluates a degraded TRU waste container failure during retrieval (LANL 1996n) in support of the TWISP. While all waste containers are examined for signs of degradation and are stabilized as necessary before retrieval, it is assumed that the bottom of a degraded waste drum could fail. The FSAR retrieval accident scenario frequency is based on 20,000 waste handling events per year, a waste handling accident frequency of 1×10^{-5} per container handling event, and a conditional probability of 1×10^{-2} of involving a drum with greater than 100 PE-Ci. For this analysis the source term was based on: (1) the current maximum TRU waste container of 658 PE-Ci (LANL 1996n); (2) a damage ratio of 0.5, based on engineering judgement for a degraded drum and cited drum drop tests; (3) an airborne release fraction of 0.001; (4) a respirable fraction of 0.1; and (5) a leakpath factor of 1.0.

The SAR for the WCRR Facility analyzes a postulated waste drum puncture accident in the outdoor staging area (LANL 1995e). It is assumed that a forklift tine punctures a waste drum being loaded on or off the bed of a truck. Because a drum grapple will be used to handle drums at all times when the drums are not palletized, the SAR concludes a scenario of this type is not credible for other drum handling operations. The SAR puncture accident scenario frequency is based on 200 movements of palletized drums per year and a waste handling accident frequency of 1×10^{-5} per container handling event. The source term was based on: (1) the proposed WCRR Facility limits for plutonium mixes or individual radionuclides (DOE Standard 1027-92 Hazard Category 3 threshold limits, WIPP WAC fissile gram equivalent limit of 325 grams), (2) a damage ratio of 0.05 (puncture of a nondegraded drum), (3) an airborne release fraction of 0.001, (4) a respirable fraction of 0.05, and (5) a leakpath factor of 1.0.

The SAR for the Radioactive Materials Research, Operations, and Demonstration Facility evaluates a postulated accident involving a forklift dropping a single TRU waste container (outside) from greater than four feet (which is the qualification limit for DOT Type A containers) (LANL 1996i). The SAR drum drop accident scenario frequency is based on 5,000 waste movements per year, a waste handling accident frequency of 1 x 10^{-5} per movement, and a conditional probability of 1 x 10^{-1} of involving a maximally loaded drum (1,000 PE-Ci). The source term was based on: (1) the previous WIPP WAC container limit of 1,000 PE-Ci, (2) a damage ratio of 0.1 (drop of a nondegraded drum), (3) an airborne release fraction of 0.001, (4) a respirable fraction of 0.05, and (5) a leakpath factor of 1.0.

The SA for the NDA/NDE Facility analyzes a design basis accident involving the puncture of a TRU waste drum by a forklift tine (LANL 1996j). A supplemental analysis is presented in the SA appendix for a smaller breach due to a drum grappler accident. The postulated accident frequency is based on a throughput of 5,000 drums per year (interim operation limit) and a forklift tine or grappler puncture conditional frequency of 1 x 10^{-5} or 1 x 10^{-6} per movement, respectively. The source term was based on the maximum radionuclide inventory for a drum (200 grams of plutonium-239, or 40 grams of plutonium-238, or 19 grams of americium-241).

No Action Alternative Frequency Analysis

Legacy waste (current dome storage) requiring characterization is estimated to involve six forklift handling operations: (1) loading onto a truck for transfer to an on-site location for assay verification, (2) unloading of the transfer truck for assay verification, (3) waste drum loading onto a transfer truck for movement to interim storage (Area G), (4) unloading of the transfer truck for interim storage, (5) waste drum movement to a staging area for shipment to WIPP, and (6) waste drum movement for loading a TRUPACT-II for shipment to WIPP.

Legacy waste (earthen-covered storage) requiring characterization/treatment is estimated to involve seven forklift handling operations: (1) retrieval of drum to laydown area, (2) drum movement for gas venting, (3) loading onto a truck for transfer to an on-site treatment location (such as the drum preparation facility), (4) unloading of the transfer truck for waste treatment, (5) waste drum movement for final NDA/NDE, (6) waste drum loading and unloading for interim storage (dome), and (7) waste drum loading and unloading of a transfer truck and subsequent movement for loading a TRUPACT-II for shipment to WIPP.

Legacy waste (earthen-covered storage) requiring overpacking/repackaging is estimated to require the same number of forklift handling operations as legacy waste that requires characterization.

The pre-decisional draft of the SWEIS Alternatives Document, Waste Management Key Facility (LANL 1997c), indicates that the newly generated waste volume for the No Action Alternative over the ten-year SWEIS time frame will total an estimated 6.61 x 10^{5} gallons (2,500 cubic meters). This is equivalent to 12,018, 55-gallon drums. The entire legacy waste (dome and earthen covered) volume of approximately 2.38 x 10^{6} gallons (9,000 cubic meters) is assumed shipped to WIPP during the SWEIS period. The legacy waste volume is equivalent to 43,273, 55-gallon drums, of which 21,136, 55-gallon drums (4,400 cubic meters) are in earthen covered storage (LANL 1997c).

It is estimated that there will be approximately 8,413 (12,018 x 7/10) waste drum handlings per year for newly generated TRU waste. Similarly, for dome legacy waste, it is estimated that there will be approximately 11,069 ([43,273 - 21,136] x 5/10) waste drum handlings per year. Earthen-covered legacy waste movements are estimated to total 21,137 (21,137 x 10/10) per year. Thus, the No Action Alternative is estimated to total 40,619 TRU waste handling (forklift) events per year. This is consistent with the 30,000-plus waste handling events identified in the cited LANL safety documentation.

Based on DOE system operating experience, the waste handling accident frequency is estimated as 1 x 10^{-5} per container handling event. This conditional accident frequency is cited in multiple LANL safety documents, including the TA–54 TWISP FSAR (LANL 1996n), the TA–54 Area G SAR (LANL 1995f), and the WCRR Facility FSAR (LANL 1995e). Additionally, the TA–54 Area G SAR indicates that less than 1 percent of all TRU waste containers in the existing Area G inventory exceed 75 PE-Ci in radioactive material content (LANL 1995f). Thus, it can be concluded that the conditional probability of a handling accident involving a high radioactive content drum is less than 1 percent. With the foregoing information, the frequency of a drum failure/ puncture due to a forklift accident can be calculated as:

$$F_{FAILURE} = N_{FEVENTS} \times C_{PFACC} \times C_{PHI/AVG}$$

where:

$N_{FEVENTS}$ = Number of forklift handling events per year

C_{PFACC} = Conditional probability of a forklift accident resulting in a container failure

$C_{PHI/AVG}$ = Conditional probability of accident involving an average or high radioactive content container

Substituting the above values, the annual frequency for a drum failure/puncture at LANL is:

High Radioactive Content Container:

$$F_{FAILURE} = N_{FEVENTS} \times C_{PFACC} \times C_{PHI/AVG}$$

$$F_{FAILURE} = 40{,}619 \times (1 \times 10^{-5}) \times 0.01$$

$$F_{FAILURE} = 0.0041 \text{ per year}$$

Average Radioactive Content Container:

$$F_{FAILURE} = N_{FEVENTS} \times C_{PFACC} \times C_{PHI/AVG}$$

$$F_{FAILURE} = 40{,}619 \times (1 \times 10^{-5}) \times 0.99$$

$$F_{FAILURE} = 0.4 \text{ per year}$$

Expanded Operations Alternative Frequency Analysis

The pre-decisional draft of the SWEIS Alternatives Document, Waste Management Key Facility (LANL 1997c), indicates that Expanded Operations Alternative waste management practices and the mixed LLW waste generation rate will be comparable to the No Action Alternative. However, newly generated TRU waste volumes are expected to double to 1.35 x 10^{6} gallons (5,100 cubic meters) from those in the No Action Alternative. This is equivalent to 24,545, 55-gallon drums.

It is estimated that there will be approximately 17,182 (24,545 x 7/10) waste drum handlings per year for newly generated TRU waste. TRU waste drum handlings for legacy TRU waste will be the same as the No Action Alternative because waste management practices will be the same for both alternatives. Thus, the Expanded Operations Alternative is projected to total 49,388 (17,182 + 11,069 + 21,137) TRU waste handling (forklift) events per year.

With a revised number of TRU waste handling events for the Expanded Operations Alternative, the frequency ($F_{FAILURE}$) of a postulated drum failure/puncture can be estimated as:

High Radioactive Content Container:

$$F_{FAILURE} = N_{FEVENTS} \times C_{PFACC} \times C_{PHI/AVG}$$

$$F_{FAILURE} = 49{,}388 \times (1 \times 10^{-5}) \times 0.01$$

$$F_{FAILURE} = 0.0049 \text{ per year}$$

Average Radioactive Content Container:

$$F_{FAILURE} = N_{FEVENTS} \times C_{PFACC} \times C_{PHI/AVG}$$

$$F_{FAILURE} = 49{,}388 \times (1 \times 10^{-5}) \times 0.99$$

$$F_{FAILURE} = 0.49 \text{ per year}$$

Reduced Operations Alternative Frequency Analysis

The pre-decisional draft of the SWEIS Alternatives Document, Waste Management Key Facility (LANL 1997c), indicates that Reduced Operations Alternative waste management practices and the mixed LLW waste generation rate will be comparable to the No Action Alternative. However, TRU waste volumes are expected to total 5.02×10^5 gallons (1,900 cubic meters), almost 25 percent less than those for the No Action Alternative. This is equivalent to 9,127, 55-gallon drums.

It is estimated that there will be approximately 6,389 (9,127 x 7/10) waste drum handlings per year for newly generated TRU waste. TRU waste drum handlings for legacy TRU waste will be the same as the No Action Alternative because waste management practices will be the same for both alternatives. Thus, the Reduced Operations Alternative is projected to total 38,595 (6,389 + 11,069 + 21,137) TRU waste handling (forklift) events per year.

With a revised number of TRU waste handling events for the Expanded Operations Alternative, the frequency ($F_{FAILURE}$) of a postulated drum failure/puncture can be estimated as:

High Radioactive Content Container:

$$F_{FAILURE} = N_{FEVENTS} \times C_{PFACC} \times C_{PHI/AVG}$$

$$F_{FAILURE} = 38{,}595 \times (1 \times 10^{-5}) \times 0.01$$

$$F_{FAILURE} = 0.0039 \text{ per year}$$

Average Radioactive Content Container:

$$F_{FAILURE} = N_{FEVENTS} \times C_{PFACC} \times C_{PHI/AVG}$$

$$F_{FAILURE} = 38{,}595 \times (1 \times 10^{-5}) \times 0.99$$

$$F_{FAILURE} = 0.38 \text{ per year}$$

Greener Alternative Frequency Analysis

The pre-decisional draft of the SWEIS Alternatives Document, Waste Management Key Facility (LANL 1997c), indicates that the Greener Alternative waste management practices and waste generation rates for mixed LLW and TRU waste will be comparable to those for the No Action Alternative. On this basis, it is expected that TRU waste handling and the associated frequency of a potential container failure will be the same as in the No Action Alternative.

Uncertainties and Sensitivities Affecting the Frequency of RAD–09

Uncertainties include broad characterization of drum handling events by waste category type, the extent that particular drum movements involve multiple drums (thus reducing the number of drum handlings), and the likelihood that all legacy TRU waste is shipped to WIPP (and the associated handlings at LANL) during the LANL SWEIS time frame. Drum movement characterization assumptions were chosen to provide an upper estimate of the frequency of occurrence for the postulated accident and are reasonably conservative when compared with the number of drum movements identified in LANL safety documentation.

Source Term Calculations

Currently, the average TRU radioactive material content per waste container is 8.9 PE-Ci (LANL 1995f). Revision 5 of the WIPP WAC limits the maximum plutonium-239 equivalent activity for untreated CH-TRU waste to be received by the facility to 80 PE-Ci per drum, if not overpacked. The WIPP WAC previously allowed up to 1,000 PE-Ci per waste container. Based on the existing inventory, the maximum container of TRU waste has 658 PE-Ci of radioactive material (LANL 1996n).

Source Term for High Radioactive Content Container. The source term for a postulated accident involving a high radioactive content TRU container is based on the identified maximum drum of TRU waste (658 PE-Ci) to be managed at LANL. From the above discussion, it is clear that this will provide a bounding source term value. As noted in section 3, the frequency of occurrence calculation accounts for the likelihood (or lack thereof) that the postulated accident would involve a drum with a high radioactive material content. (Note that RAD–07 was a fire involving 62 drums, with their expected PE-Ci content; whereas, this accident involves a single drum of the maximum PE-Ci content.)

A damage ratio of 1.0 is conservatively assumed for the postulated accident to account for a degraded drum failure during retrieval handling activities. The TWISP SAR (LANL 1996n) accounted for the potential of a degraded drum, but interpreted drum drop tests for nondegraded drums on an unyielding surface to justify a somewhat less conservative value for the damage ratio (0.5). Bounding values for the airborne release fraction and respirable release fraction of 0.001 and 0.1, respectively, are assigned and are representative of the situation where surface contaminated material is packaged in a robust container (e.g., drum) that fails due to impact with the floor. The accident is assumed to occur outdoors such that the leakpath factor has a value of 1.0. With the above information, the initial source term equation can be quantified as follows:

Initial Source Term = MAR x DR x ARF x RF x LPF

= 658 PE-Ci x 1.0 x 0.001 x 0.1 x 1.0

= 0.066 PE-Ci

The suspension MAR equals the initial MAR, minus the initial source term (0.066), which for this case effectively equals the initial MAR. The suspension DR and LPF have the same values (1.0) as in the initial source term calculation. The ARR and RF are assigned values of 4×10^{-5} and 1.0, respectively, based on bounding resuspension factors for surface contaminated material exposed to ambient conditions (DOE 1994d). Thus, the suspension source term can be quantified as:

Suspension Source Term = MAR x DR x ARR x 24 hrs x RF x LPF

= 658 PE-Ci x 1.0 x (4×10^{-5}) x 24 hrs x 1.0 x 1.0

= 0.63 PE-Ci

It can be seen that the suspension source term is an order of magnitude greater than the initial source term. The calculated suspension source term is highly conservative considering that DOE Handbook 3010-94 assigns the same suspension value for surface contaminated materials as for powders and the assumption that the spill is not controlled for 24 hours. This is conservative since the HAZMAT team would be expected to clean up the spill much sooner than 24 hours.

Source Term Analysis for Average Radioactive Content Container. The source term for this postulated accident is based on a conservative estimate of the average radioactive content (12 PE-Ci) of a TRU waste container, as noted above. Other initial source term parameters for the high radioactive content container would be applicable and are retained for the analysis of an average radioactive content container. Thus, the initial source term is quantified as:

Initial Source Term = MAR x DR x ARF x RF x LPF

= 12 PE-Ci x 1.0 x 0.001 x 0.1 x 1.0

= 0.0012 PE-Ci

The suspension MAR equals the initial MAR, minus the initial source term (0.0012), which for this case effectively equals the initial MAR. The suspension DR and LPF have the same values (1.0) as in the initial source term calculation. The ARR and RF are assigned values of 4×10^{-5} and 1.0, respectively, based on bounding resuspension factors for surface contaminated material exposed to ambient conditions (DOE 1994d). Thus, the suspension source term can be quantified as:

Suspension Source Term = MAR x DR x ARR x 24 hrs x RF x LPF

= 12 PE-Ci x 1.0 x (4×10^{-5}) x 24 hrs x 1.0 x 1.0

= 0.0115 PE-Ci

As with the high radioactive content container analysis, it can be seen that the suspension source term is an order of magnitude greater than the initial source term and is conservative.

Because the source terms are based on average and maximum content containers, there are no variations across the alternatives.

Uncertainties and Sensitivities for RAD–09

This accident assumes that all of the material in a drum is spilled. This assumption is very conservative because a drum puncture due to a drop or a puncture with a forklift is not likely to spill the entire contents of a TRU waste container. The conservative assumption, however, would bound this instance or the consequences of an event where more than one drum would be punctured. The ARF, ARR, and RF values also bound the type of material that could be involved in the accident. Thus, the accident represents a bound on the variations that could occur with a drum puncture and is still considered conservative.

The suspension term is the dominate contributor to the doses for this event. Because of the nature of the drum puncture event, the cleanup can be easily controlled and evaluated. If cleanup is assumed to take 1-hour as opposed to 24 hours, the suspension terms would then change as shown in Table G.5.6.9–1.

If the results are scaled by the source and suspension terms consistent with a 1-hour cleanup period, the consequences would be as given in Table G.5.6.9–2.

The results for the 24-hour cleanup are very conservative. Because of the limited nature of the accident, the expectation is for cleanup to

begin immediately after the accident and to be completed within 1 hour.

Consequences of RAD–09 for Facility Workers and the Public

The consequences for facility workers and the public are discussed separately. All facility operations personnel receive emergency preparedness training specific to the facility and for procedures applicable to all of LANL. The Emergency Action Plan directs personnel to move as quickly as possible in an upwind direction away from any hazardous situation and to make appropriate notifications to the Emergency Management and Response (EM&R) Group Office as soon as they are safely away from the hazard. Once notified, the EM&R Office assumes all elements of emergency response and coordination.

The postulated accident would result in an immediate release to the surrounding area. The primary hazard would be airborne suspension of respirable radioactive material. The dose to the involved worker would be dependent on the ambient conditions of the accident and how they affect dilution of the radioactive material in the air (e.g., outdoors, wind speed, confined area, indoors or outdoors), the time for the worker to identify a release and to vacate the immediate area, and any impediments (accident related) to the worker's movement away from the release. The number of workers potentially exposed would depend on the location of the accident and the nature of the activity being conducted at the time of the accident (e.g., retrieval versus waste staging versus truck loading/unloading).

No acute fatalities are predicted to result from a postulated accident involving an average or a high radioactive content drum. The mean collective population dose is projected to total 4.4 person-rem (TEDE) for an accident involving an average radioactive content drum, resulting in 0.0022 excess LCF. For a high radioactive content drum, accident impacts are projected to total 230 person-rem (TEDE), resulting in 0.12 excess LCF. Mean projected doses for MEIs (and their associated locations) and ground contamination levels are presented in Tables G.5.6.9–4 and G.5.6.9–5, respectively. Table G.5.6.9–3 summarizes the modeling results for RAD–09.

G.5.6.10 *RAD–10, Plutonium Release from Degraded Vault Storage Container at TA–55–4*

General Scenario Description

TA–55–4 is the Plutonium Facility at LANL. Among the activities at TA–55–4 is the storage of a large quantity of plutonium in vault rooms in the basement of the building. Accident scenario RAD–10 involves dropping a plutonium container during retrieval from the vault. The container is a degraded container that fails and disperses plutonium into the atmosphere of the vault. If this sequence of events occurs during normal operations with both the HVAC and HEPA systems in operation, the release will be filtered by several stages of HEPA filters, and the release to the environment will be less than 10^{-8} grams. Under the SWEIS screening criteria, this scenario would screen. In order to have a release to the environment, the HEPA filters would have to be failed or the facility would have to lose power, placing the facility into a breathing mode. The breathing mode results in an LPF of 0.011 (LANL 1996k), while the LPF with the HEPA filters failed and the HVAC system in operation is assumed to be 1.0 (LANL 1996k). The LPF under normal conditions with both HVAC and HEPA filters in operation is 8×10^{-13} for a multi-stage HEPA filter system (LANL 1996k).

As a result of implementation of the Defense Nuclear Facilities Safety Board (DNFSB) Recommendation 94-01 by DOE, LANL will be retrieving from storage, stabilizing, and repackaging a large amount of plutonium (DNFSB 1994). LANL began its program with 8,670 containers of plutonium, and had completed about 17 percent of the program as of early 1996. There are approximately 7,200 remaining containers to be retrieved and repackaged by the year 2002. This represents a rate of about 1,200 per year over the 6-year period from 1996 to 2002.

LANL has already completed a 100 percent visual inventory inspection of the packages so far retrieved, and found 361 containers with some defect. Of these, 82 appeared to have lost outer containment.

LANL has approached the degraded container issue from a systems reliability standpoint. There is a total of 7,200 plutonium containers remaining in the vault. Of these, 5.5 percent are projected to have a failed outer container (i.e., a total of 396). Of these, an estimated 2 percent also have failed inner containers (i.e., a total of 8) (LANL 1996p). DOE Standard 3013-96 (DOE 1996e) addresses the requirements for containers for long-term (at least 50 years) storage of plutonium. To meet the standard, plutonium-bearing materials must be in stable forms and packaged in containers designed to maintain their integrity under both normal storage conditions and anticipated handling accidents for at least 50 years (DOE 1996e). The standard applies to metal, oxide, and alloys containing at least 50 percent plutonium by mass, and containing less than 3 percent plutonium-238 by mass (DOE 1996e). The quantity of metal per container should be as close as practical to, but not exceed, 9.68 pounds (4.40 kilograms). Stored metal pieces are required to have thicknesses greater than 0.04 inch (1.0 millimeter) and have specific surface areas less than 71 square inches per pound (1.0 square centimeters per gram) to reduce potential pyrophoric tendencies (DOE 1996e). The quantity of oxide by container should be as close as practical to, but not exceed, 10.97 pounds (5.00 kilograms), representing the plutonium dioxide equivalent of 9.68 pounds (4.40 kilograms) of plutonium metal. The oxides are required to be thermally stabilized with less than 0.5 percent mass loss-on-ignition (DOE 1996e). The containers are required to include a minimum of two nested sealed containers and have at least one container that remains leak-tight after a free drop from a

30-foot (9-meter) height into a flat, essentially unyielding, horizontal surface (DOE 1996e). The containers are required to have a cylindrical geometry not exceeding 4.9 inches (12.5 centimeters) outside diameter or 10 inches (25.4 centimeters) external height (DOE 1996e). Once the plutonium is repackaged in DOE Standard 3013-96-compliant containers, the likelihood of RAD–10 will be significantly reduced.

The TA–55 SAR (LANL 1996k) analyzes this scenario in detail. The SAR places the unmitigated scenario (i.e., with HVAC operating and HEPA filters failed) into the frequency bin from 10^{-4} to 10^{-2} per year. The SAR quantified the source term as follows (LANL 1996k):

Initial Source Term
= MAR x DR x ARF x RF x LPF

= 4,500 x 1 x 0.002 x 0.3 x 1

= 2.7 grams of plutonium

The SAR evaluated the dose to the off-site MEI, located at the Royal Crest Trailer Court, 2,952 feet (900 meters) from TA–55–4, using 95th percentile meteorology. The calculated exposure was 8.1 rem TEDE (LANL 1996k).

No Action Alternative Frequency Analysis

There are two types of containers for which analyses must be made. Most containers in the vault are closed such that some pre-existing failure would be necessary in order to get a release from dropping the container. This applies to 7,200 total containers, less those that do not meet this criterion (1,370), or a total of 5,830 containers. The frequency of this scenario can be evaluated using the following equation:

$$F_{DROP} = N_{CONT} \times H_{DROP} \times C_{INNER} \times C_{OUTER} \times C_{HEPA} \times H_{HVAC}$$

where:

F_{DROP} = Frequency of dropped container resulting in unfiltered release of plutonium

N_{CONT} = Number of containers handled per year

H_{DROP} = Human error probability (HEP), dropping a container

C_{INNER} = Conditional probability of a degraded inner container

C_{OUTER} = Conditional probability of a degraded outer container

C_{HEPA} = Conditional probability of HEPA failure

H_{HVAC} = Human error probability, failure to terminate HVAC system with HEPA filters failed and stack monitor alarming

The number of containers handled per year, based on the DNFSB 94-1 program being completed in the year 2002, is 1,200 containers per year. Of these, 5,830 have seals that would require a pre-existing failure, or a rate of 972 per year. It is assumed that containers are handled only once before being placed into DOE Standard 3013-96 containers.

The HEP in dropping a plutonium container is estimated at 0.001 per demand. This value is applicable to a checker failing to check the status of equipment if the status of the equipment affects one's safety when performing the task (Swain and Guttmann 1983). This error rate is judged to most closely represent the circumstances involved in retrieving a container of plutonium from the vault at TA–55–4.

The conditional probabilities of failed outer and inner containers are estimated at 0.055 and 0.02, respectively, based on LANL-specific data (LANL 1996p). The conditional probability of the HEPA system being failed is evaluated based on LANL-specific data from 1990 to1994 (LANL 1990b, LANL 1991b, LANL 1994c, LANL 1994d, and LANL 1995h), and considered a two-stage HEPA filter system (LANL 1996k). The 1990 to 1994 data indicate a 5 percent failure rate for HEPA filters. However, there is differential pressure measuring instrumentation installed between the HEPA filters in series, which alarms when it detects failure of a filter. In order for HEPA filters in series to fail, both the HEPA filters and the differential pressure instrumentation indicating failure of filters must fail. Considering two filters in series, this yields a HEPA failure rate of 0.05 x 0.05, or 2.5×10^{-3} for the HEPA filters, and an additional conditional probability of 5×10^{-3} for failure of a single instrument channel covered by a preventive maintenance program and related administrative procedures (Mahn et al. 1995). Thus, the overall HEPA filter failure probability is $(2.5 \times 10^{-3}) \times (5 \times 10^{-3})$, or 1.3×10^{-5} per demand.

H_{HVAC} is a proceduralized action. The Human Reliability Handbook identifies a basic HEP for these circumstances of 0.025 per demand (Swain and Guttmann 1983). A shift supervisory function also would be staffed and would be expected to respond if the operator does not. The HEP for this function is 0.1 (Swain and Guttmann 1983). The total HEP for H_{HVAC} is 0.025 x 0.1, or 2.5×10^{-3} per demand.

Based on these considerations, the above equation can be quantified as follows:

$$F_{DROP} = N_{CONT} \times H_{DROP} \times C_{INNER} \times C_{OUTER} \times C_{HEPA} \times H_{HVAC}$$

$$= 972 \times 0.001 \times 0.055 \times 0.02 \times (1.3 \times 10^{-5}) \times (2.5 \times 10^{-3})$$

$$= 3.5 \times 10^{-11} \text{ per year}$$

The frequency of such a scenario affecting only facility workers is much higher because the C_{HEPA} and H_{HVAC} terms disappear from the frequency equation (it is not necessary to have HEPA or HVAC failures to affect workers inside the facility). Quantified for workers, the frequency becomes 1.1×10^{-3} per year.

The remaining 1,370 containers are food pack cans, dressing jars, or other similar containers. These containers were used to pack plutonium metal (LANL 1996k). In addition, these containers lack a hermetic seal, which can lead to oxidation of the metal and failure of the inner containers. Corrosion of the metal by organic compounds caused by alpha-particle-induced decomposition of the plastic also can occur. Finally, degradation of taped seals on containers and plastic bags around the inner containers makes the containers susceptible to rupture during handling or if dropped (LANL 1996k). For these reasons, the conditional probability of a degraded container is taken as 1.0.

The following equation applies:

$$F_{DROP} = N_{CONT} \times H_{DROP} \times C_{HEPA} \times H_{HVAC}$$

where:

F_{DROP} = Frequency of dropped container resulting in release of plutonium

N_{CONT} = Number of containers handled per year

H_{DROP} = Human error probability, dropping a container

C_{HEPA} = Conditional probability of HEPA failure

H_{HVAC} = Human error probability, failure to terminate HVAC system with HEPA filters failed and stack monitor alarming

The number of containers is 1,370, divided by the 6-year period of the 94-1 program, or a rate of 228 per year.

Based on the information presented above, the equation can be quantified as follows:

$F_{DROP} = N_{CONT} \times H_{DROP} \times C_{HEPA} \times H_{HVAC}$

$= 228 \times 0.001 \times (1.3 \times 10^{-5}) \times (2.5 \times 10^{-3})$

$= 7.5 \times 10^{-9}$ per year

Clearly, these containers dominate the overall frequency. However, the overall frequency is extremely low. Based on detailed frequency quantification, it was determined that the qualitative binning of this sequence into the 10^{-6} to 10^{-4} per year frequency bin in the TA–55 SAR is excessively conservative, and that this scenario screens on low frequency. On a deterministic basis, so many failures and/or human errors are required for a release to the environment to occur from this scenario that the scenario is not credible.

The frequency of such a scenario affecting a worker is different because the C_{HEPA} and H_{HVAC} terms disappear from the frequency equation (it is not necessary to have HEPA or HVAC failures to affect workers inside the facility). Quantified for workers, the frequency becomes 0.228 per year, or about one every 5 years. This would place this scenario into an expected occurrence. The quantification is conservative in that it assumes every time a container is dropped a spill results. This scenario has been included as a strictly worker accident in section G.5.7.5.

Uncertainties and Sensitivities Affecting the Frequency of RAD–10

Regardless of the sensitivities and uncertainties in the frequency of this scenario, the absolute frequency is extremely small and would not result in a credible scenario frequency even if more conservative values were used in quantification. The scenario is screened from further analysis.

Source Term Calculations

Source term calculations followed the general DOE Handbook 3010-94 process, with the ARF and RF selected therefrom (DOE 1994d, page 4-9) and are also those used for this spill. The DR is 1 (the entire contents of the container are spilled), and the LPF = 1 with the HEPA filters failed (this is very conservative). Thus, the source term equation can be quantified as follows:

Initial Source Term = MAR x DR x ARF x RF x LPF

= 4,500 x 1 x 0.002 x 0.3 x 1

= 2.7 grams weapons-grade plutonium

The suspension source term calculation also is performed according to DOE Handbook 3010-94. The ARR and RF values for a powder spill are 0.00004 and 1.0, respectively, for a homogeneous bed of powder exposed to normal process ventilation flow (it is conservative to assume that the ventilation system is not turned off). Quantification is for 24 hours (this is potentially very conservative for a spill inside the facility). The suspension source term equation is quantified as follows:

Suspension Source Term = MAR x DR x ARR/hr x 24 hrs x RF x LPF

= (4,500 - 2.7) x 1 x 0.00004 x 24 x 1 x 1

= 4.3 grams of weapons-grade plutonium

There are no differences in source term across the alternatives.

Uncertainties and Sensitivities Affecting the Source Term for RAD–10

The assumption of an LPF of 1 with the ventilation on and the HEPA filters failed is extremely conservative. It would be expected that, by procedure in response to stack radiation alarms, the ventilation system would be shut down as soon as the HEPA filter failure was discovered, which would take the LPF from 1 to 0.011. The assumption of a 24-hour suspension period for this process-oriented event is also potentially very conservative because the spill would be expected to be cleaned up well before 24 hours.

Another significant uncertainty is the quantity of plutonium in the container. The analysis assumes the maximum allowed (4,500 grams). In reality, the amount could be smaller, resulting in a smaller source term.

Consequences of RAD–10 for Facility Workers and the Public

Consequences are discussed separately for facility workers and the public. The workers retrieving the container that is dropped and fails could be exposed to plutonium inhalation, with substantial doses possible depending upon the usage of PPE and the speed with which the worker(s) is able to exit the immediate area.

The public consequences are summarized in Table G.5.6.10–1. It must be understood that the worker consequences occur at a much higher frequency. As indicated above, the likelihood of public consequences from this scenario is extremely small and considered to be incredible under NEPA practice. The likelihood of worker consequences is much higher, ranging from 1.1×10^{-3} to 0.22 per year for the two contributing scenarios.

No acute fatalities are predicted to result from the postulated accident. The mean collective population dose is projected to total 560 person-rem (TEDE), resulting in 0.28 excess LCFs. Mean projected doses for MEIs (and their associated locations) and ground contamination levels are presented in Tables G.5.6.10–2 and G.5.6.10–3, respectively.

G.5.6.11 *RAD–11, Container Breach After Detonation of Plutonium-Containing Assembly at DARHT*

General Scenario Description

General information on the DARHT Facility and its function and mission is provided in RAD–04. As stated in RAD–04, the DARHT EIS included analysis of potential accidents, including bounding accidents that were selected and evaluated on a “what-if” basis (DOE 1995a) based on potential consequences, with little or no consideration of the frequency of occurrence, though the likelihood of occurrence would be small. Scenario RAD–11 represents the failure of a double-walled steel containment system following the detonation of a plutonium-containing assembly. As noted earlier in the DARHT EIS, in related safety analyses these accidents have been evaluated to be not credible (probability less than 10^{-6} per year). Although some hundreds of dynamic experiments may be conducted per year, only a small number will contain plutonium (LANL 1996m), and these experiments would not reasonably be expected to result in any release of plutonium to the environment (DOE 1995a).

As explained in greater detail in the DARHT EIS, the accident scenario RAD–11 involves the failure (breach) of a double-walled steel containment system following the planned detonation of a plutonium-containing assembly to be radiographed at DARHT or at the existing PHERMEX Facility located a short distance away. Some dynamic experiments involve plutonium in order to obtain needed information and understanding associated with nuclear weapons aging and continued assurance of weapon safety and performance (DOE 1995a). As a matter of policy, these experiments will always be conducted inside a double-walled steel containment system consisting of an inner confinement vessel and an outer safety vessel to prevent plutonium release; furthermore, the

60.0 to 80.0 km	2.9×10^{0}

experiments will always be arranged and conducted in such a manner that a nuclear explosion could not result (DOE 1995a).

The impacts of the hypothetical RAD–11 containment breach scenario are similar to but less than those for the hypothetical uncontained detonation scenario of RAD–04. For the RAD–11 scenario, no immediate worker deaths would be anticipated due to the high-explosives blast causing the containment breach because involved workers would be sheltered at the time of test execution. The human health impacts to the public and to noninvolved workers are dominated by the explosive aerosolization of plutonium, which is then released through a breach in the double-walled containment and atmospherically dispersed. In the DARHT EIS, DOE examined the environmental consequences that could occur if the outer vessel were breached with a 1-inch hole (DOE 1995a). Up to tens of excess LCFs based on a 50-year committed dose would result from this hypothetical scenario, depending on the population sector assumed to be exposed due to extant winds. Impact analysis for this SWEIS is taken directly from the analysis DOE has already performed and received comment on from the public; other agencies; and state, local, and Tribal governments in the DARHT EIS. For the convenience of the public and the decision maker, some of that information also is directly reproduced in this SWEIS (section G.5.6.4). The methodology and all impacts associated with this hypothetical containment failure are principally contained in Chapter 5 and Appendixes H, I, and J of that EIS; additional information is contained in a classified appendix.

No Action Alternative Frequency Analysis. The frequency of this scenario is evaluated as incredible (i.e., less than 10^{-6} per year), as was indicated the DARHT EIS (DOE 1995a). This frequency is corroborated by DOE safety analyses.

Expanded Operations, Reduced Operations, and Greener Alternatives Frequency Analysis. No differences in frequency across the SWEIS alternatives have been identified that would alter the designation of this scenario as having a frequency of less than 10^{-6} per year, as discussed in the DARHT EIS. The frequency categorization for the No Action Alternative is assumed to be applicable across the SWEIS alternatives.

Source Term Calculations. As described in the DARHT EIS (DOE 1995a), analysis of this hypothetical accident is documented in a classified appendix to that EIS. While the resulting impacts, as well as unclassified calculations, assumptions, and modeling methods, are contained in the unclassified sections of the EIS, some details of such experiments, including some associated with the source terms for this accident scenario, are classified.

Consequences of RAD–11 for Facility Workers and the Public. Impacts to involved workers, noninvolved workers, public populations and MEIs, were described in the DARHT EIS. Under this scenario, there would be no impact to workers, who would be sheltered during the detonation and subsequent breach of the vessel system.

Predominant human health impacts to noninvolved workers or the public would stem from exposure to aerosolized and dispersed material. Impacts to noninvolved workers at distances of 2,500 and 1,300 feet (750 meters and 400 meters) were evaluated (DOE 1995a). Doses to noninvolved workers were estimated to be 60 rem and 20 rem for a worker at 1,300 feet and 2,500 feet (400 meters and 750 meters), respectively; corresponding probabilities of excess LCFs would be 0.02 and 0.009, respectively, for such individuals. LANL administratively controls access to explosives areas by noninvolved individuals and has a set of established hazard radii for protection of personnel from fragment injury from explosives experiments, based on DOE principles. It was estimated that a noninvolved worker would likely be no closer than 2,500 feet (750 meters). The public MEI located at State Road 4 was calculated to receive 14 rem, with a resulting probability of an excess LCF of 0.007 (DOE 1995a).

The population exposure for the most populated sector (which includes White Rock and Santa Fe) was estimated to be between 210 and 560 person-rem for 50th and 95th percentile meteorological conditions, respectively, resulting in negligible excess LCFs (DOE 1995a). While diffusion of material across an entire directional sector was taken into account, it was assumed that all of the community populations were located at or near to the plume center line, a conservative assumption that results in an overestimate of impacts (DOE 1995a). Impacts for both workers and the public also can be found in tabular form in Table I-10 and Table I-11 in the DARHT EIS, which is reprinted for convenience in this SWEIS in section G.5.6.4. These tables show impacts from both the uncontained detonation and containment breach scenarios on a what-if basis. Population dose and impacts to other communities also were calculated for the inadvertent detonation accident, which is the bounding case, and can be seen in RAD–04 (section G.5.6.4). Table G.5.6.11–1 summarizes these results.

G.5.6.12 *RAD–12, Plutonium Release from a Seismically Initiated Event*

General Scenario Description

The accident scenario discussed here is an explosively driven release of plutonium from building TA–16–411. This scenario is similar to that of RAD–04, but would be specific to the TA–16–411 facility because it supports existing high explosives operations. The explosive dispersal would be initiated by the collapse of appropriate parts of this structure during an earthquake, during one of the short periods when an explosive assembly including plutonium would reside in this facility. In this scenario, the seismic collapse is postulated to cause high explosives to detonate and, in the process, aerosolize a portion of the plutonium as respirable particles. Although it could be expected from the collapse of the building that a portion of the material (including respirable particles) would be trapped by the debris and unavailable for atmospheric transport. For this case it was conservatively assumed that there was no trapping of material relative to an uncontained, open-air explosives release.

The scenario is considered marginally credible based on recent safety analyses, and may fall at or below the screening criteria cutoffs (to "incredible") as more detailed analysis is developed. New studies have demonstrated that the frequency of such an accident would

TABLE G.5.6.11–1.—*Summary Results for Scenario RAD–11*

ALTERNATIVE	ACCIDENT FREQUENCY	INTEGRATED POPULATION DOSE (PERSON-REM, TEDE)	EXCESS LCFS
No Action	$< 10^{-6}$	210	.01
Expanded Operations	$< 10^{-6}$	210	01
Reduced Operations	$< 10^{-6}$	210	01
Greener	$< 10^{-6}$	210	01

decrease based on more detailed and thorough (yet still conservative) evaluation of the structural robustness of the vault of building TA–16–411 (the only part of the structure where these materials would reside) to withstand earthquakes. These studies are currently under review by LANL and DOE. Similarly, other factors of conservatism are included in the current assessment of probability of this scenario.

No Action Alternative Frequency Analysis

Because this accident scenario is a seismically initiated event, the capacity of the building to withstand an earthquake is a key factor in determining the frequency of the accident. TA–16–411 includes a vault structure attached to an older main building. Because high explosives and plutonium material would only be present within the vault structure, it is the capacity of the vault to withstand earthquakes, not that of the less-robust older part of the structure, that relate to the probability or frequency of this scenario.

The vault and its major components in TA–16–411 are known to have a significantly greater capacity to resist damage from an earthquake than the older main structure. Highly conservative analyses based on simple statistical modeling of the vault structure showed the vault would withstand earthquakes in the SITE–01 grouping of earthquake magnitudes (0.04 to 0.1 *g*), but were consistent with a low probability of failure from earthquakes of about 0.3 *g*, in the SITE–03 range. This means that we have a great deal of confidence that the vault will not fail for higher frequency earthquakes, and are therefore very conservative in estimating a failure of the vault at these stated values.

Note that in the SITE–01 estimates of the HCLPF values, the building as a whole corresponds to 0.05 *g*, which lies in the range designated as the SITE–01 grouping of earthquake magnitudes (0.04 to 0.10 *g*). The HCLPF value related to the structure as a whole is limited by the older main structure; this magnitude earthquake would correspond to a frequency of 3.5 x 10^{-3}.

The overall accident frequency is lower than the estimated earthquake occurrence frequency because of further conditional probabilities of an earthquake occurring when the high explosives components are in the vault because they are not housed in the vault on a continuous basis. Finally, these explosives are not highly susceptible to detonation from low impact mechanical shocks, such as falling debris.

Because the vault is the only relevant component of the building, the overall frequency based on this seismic analysis would be on the order of magnitude of 4 x 10^{-6}, near the screening threshold for credible accidents in this SWEIS.

More recently, a more thorough dynamic modal analysis of this structure (still based on conservative principles) performed under contract to LANL has indicated that the structure would have a high confidence of withstanding at least 0.31 *g* earthquakes. This would reduce the frequency associated with this accident scenario to about 1.5 x 10^{-6} or lower. More precise estimates of this frequency may be available by the time the Final SWEIS is prepared. At this frequency, the accident is marginally credible when conservatively analyzed. More realistic, but still conservative, assumptions could reduce this frequency to below 10^{-6}; however, to be conservative, this scenario is included in the Draft SWEIS as marginally credible.

Expanded Operations, Reduced Operations, and Greener Alternatives

Because this building will be used under all alternatives, the frequency values would remain the same.

No Action Source Term Calculations

Some details associated with the source terms for this accident scenario are classified. No credit is taken for entrapment of the material by building debris, so all of the respirable particles are considered available for atmospheric transport.

Consequences for Facility Workers

The workers in the facility would be killed by the explosion or falling debris. No doses were evaluated because it would be highly unlikely that anyone would survive such an event.

Consequences for the Public

As noted earlier, different methodologies may be used to evaluate atmospheric dispersal and human health impacts; it is understood in this analysis that there is a range of uncertainty associated such models. Conservatism is included through a variety of approximations and assumptions. For this accident scenario, the equations used to define the initial plume dimensions and plume centerline height are those recommended in *Plutonium Explosive Dispersal Modeling Using the MACCS 2 Computer Code* (Steele et al. 1997). The Julick System (Vogt 1997) derived for 164-foot (50-meter) plumes is used for determining the downwind expansion of the Σ_y and Σ_z terms. The plume meander option was not activated.

The duration of the emergency phase was defined as 1 day. It was assumed that no emergency phase mitigative actions (evacuation or sheltering) were implemented to reduce emergency phase exposures. For doses from the inhalation of resuspended particles, chronic population exposures were to be mitigated by decontamination, temporary interdiction, or condemnation of contaminated property, if doses exceeded 2 rem in the first year following the accident. This criterion is a generalization of EPA guidance that recommends dose mitigative actions if it is projected that individuals will receive 2 rem in the first year following the accident (EPA 1991).

The integrated population numbers are given for both the public within a 50-mile (80-kilometer) radius and, separately, the LANL workforce populations. Note that adding these numbers represents a conservative number. LANL employees who work at the site and live within the area are counted twice for the integrated population doses.

Table G.5.6.12–1 is a summary of the consequences for this scenario. Table G.5.6.12–2 is a summary of the overall risks for this scenario. The MEI locations calculated for this scenario are given in Table G.5.6.12–3.

G.5.6.13 *RAD–13, Plutonium Release from Flux Trap Irradiation Experiment*

General Scenario Description

The Skua fast-burst reactor, housed at Kiva #3 at Pajarito Site (TA–18–116) can be used for irradiation of experiments within a cavity in the reactor core, called a flux trap. These experiments would be carried out inside Kiva #3 (LANL 1996f). The bounding experiment modeled here is a shock rod experiment; other experiments, involving less severe conditions and far less MAR, may also be carried out in the Skua flux trap. The intent of a shock rod experiment is to measure the stress generated in a sample of fissile material by the rapid heating caused by fissions induced by the neutron pulse. The accident scenario involves a shock rod experiment in which the maximum design pulse of power is delivered to the experiment, rather than the lower intended power. The oversized pulse results in a very high energy deposition in the shock rod, resulting in melting (but not vaporization) of 6,000 grams of plutonium.

Closest Residential Population: 5.2 km	18

Note that no such experiments have been conducted to date at TA–18. Thus, the TA–18 SAR analysis concerns a capability to perform such experiments, rather than an intention to do so. (Shock rod experiments have been performed at SNL using the SPR-II fast-burst reactor, and are discussed in the SARs of both SPR-II and SPR-III.)

Shock rod experiments can be carried out using highly enriched uranium (largely, uranium-235) or plutonium (largely, plutonium-239) (LANL 1996f). However, because the expected fuel failure and resultant hazards of uranium experiments are much lower than for plutonium rods, the TA–18 SAR analysis focused on the plutonium shock-rod experiments (LANL 1996f). The SWEIS accident analysis also concerns plutonium shock rod experiments for the same reasons.

Plutonium experiments with the Skua fast-burst assembly are required to incorporate two levels of containment; but, the TA–18 SAR analysis assumes no containment (LANL 1996f and Paternoster et al. 1995). However, even if containment is used, the SAR calculations indicate that a final liquid temperature of about 3,600°F (2,000°C) is achieved. Because the melting temperature of a range of stainless steels used as glory-hole liners is 2,552 to 2,732°F (1,400 to 1,500°C), rupturing of the steel liner in the containment device would be expected, which would allow the molten plutonium to contact air. Because the ignition temperature of plutonium in air is about 930 to 1,100°F (500 to 600°C) (depending on the surface area of the plutonium), a plutonium fire would occur (LANL 1996f).

This accident scenario was analyzed in the TA–18 SAR. No accident sequence frequency was estimated or calculated in the SAR, nor was a frequency bin assignment made. Rather, the SAR stated that all of the accidents analyzed were incredible, implying a frequency of less than 10^{-6} per year. The source term was calculated assuming a release fraction of 0.001 from the melt (i.e., 6 grams of plutonium). Release into the environment was modeled based on exfiltration through the confinement structure and dispersal downwind. The source term also took into consideration the fission products generated during the burst of neutrons to the target material (LANL 1996f).

No Action Alternative Frequency Analysis

No shock rod experiments have been performed at TA–18, nor are any such experiments planned under any of the SWEIS alternatives. The TA–18 SAR analysis is more by way of providing SAR assessment space so that if the need arises, the capability to conduct shock rod experiments can be realized without a lengthy administrative delay that could otherwise be needed in order to amend the SAR. Accordingly, any frequency assignment for this accident scenario will necessarily be speculative.

Nevertheless, some perspective on the likelihood of the accident scenario can be gained by considering what sorts of failures would be necessary in order for the accident to take place. Both the TA–18 SAR and the SAR for the SPR-III facility at SNL characterize the accident as probable because it can occur at the design power level of the fast-burst reactor used to conduct the experiment (LANL 1996f). Based on DOE Standard 3009-94 (DOE 1994d), this is interpreted to mean that the accident is credible, but very unlikely, representing a design basis accident. This would place the accident scenario into the 10^{-6} to 10^{-4} per year frequency bin.

The most likely cause of the accident would be a chain of human errors leading to an excessive power level (but still within Skua design levels) being used for the experiment, although it is feasible that an undetected design or fabrication error could also lead to the accident. Typical human error rates for tasks generally are in the range of 10^{-4} to 10^{-2} (Mahn et al. 1995 and Swain and Guttmann 1983). Considering the fact that tests at TA–18 are performed under a testing plan and an experiment plan, these additional levels of administrative control suggest that the lower end of this range of human error rates is more reasonable as a basis for quantification. The probability of errors for a checker of someone else's work is expected to be higher than the probability of the original error because the checker does not normally completely redo the calculations when evaluating someone else's work. This represents a special case of dependence in human reliability analysis (Swain and Guttmann 1983). The basic recommended error rate for a checker is 0.1 when using written procedures; for a one-of-a-kind check (nonroutine), the recommended value is 0.05 because the checker would be expected to approach this task with a higher level of alertness for possible errors (Swain and Guttmann 1983).

Also important for the particular accident under evaluation here is that the opportunities for recovery from the error during the pulse operation are extremely limited once the calculation checks have been completed. This is due to the nature of the event. That is, once the experiment has been set up and the operation initiated, the neutron pulse happens in a tiny fraction of a second, and there is no chance to recover from the error or mitigate the consequences of the event (apart from emergency response).

Considering the above, the human error rate in experiment operation might be of the order of 5×10^{-7} per experiment (0.0001 x 0.05 x 0.1), assuming one initial error and two failed checks. Even this estimate implicitly assumes that all errors lead to the fuel melting outcome; this is clearly incorrect because not all operational errors are catastrophic. Clearly, a plutonium melting accident arising from a shock rod experiment is not very likely.

It is also possible that an error in maintenance or calibration could lead to a higher than intended power level being delivered to a shock rod experiment. This would also require at least two errors (the initial error and the failure of the checker to detect the error). If independence between these errors is assumed, a typical HEP for test, maintenance, and calibration activities that leaves a component or system with an unrevealed fault is 10^{-3} per demand, with a range from 3×10^{-4} to 3×10^{-3} per demand (Mahn et al. 1995), with the lower end of the range being more reasonable, given the administrative controls mentioned above. Given the unique nature of a shock rod experiment for LANL, the appropriate checker failure rate would be 0.05. This would yield a value of about 1.5×10^{-5} ($0.0003 \times 0.05 = 1.5 \times 10^{-5}$). However, not all errors are equally serious or would necessarily lead to a power level resulting in shock rod melting (e.g., some errors would lead to the inability to conduct the pulse, with an investigation into the cause being very likely to identify the error and lead to its correction.) Again, a plutonium melting accident arising from a shock rod experiment is not very likely.

Consistent with the sliding-scale approach in DOE NEPA guidance (DOE 1993b), the frequency of this accident is set to 1.6×10^{-5} per experiment for all alternatives (the sum of the conditional frequencies of the two contributing error modes). (This frequency is carried forward as one experiment per year.)

Expanded Operations, Reduced Operations, and Greener Alternatives Frequency Analysis

This accident is independent of the alternatives. The activity that could give rise to this accident has not yet been performed at LANL and is not scheduled to be performed. The accident models a capability to perform the activity. Therefore, there is no reason to assess a variation in frequency across the alternatives.

Uncertainties and Sensitivities Affecting the Frequency of RAD–13

The accident frequency calculation documented above is speculative. However, given that the experiment has not been performed at LANL and that there are no current plans to perform the experiment, the frequency estimate is considered to be representative of what might be expected for circumstances under which the experiment is conducted infrequently (once per year or less).

Source Term Calculations

The TA–18 SAR employed a respirable release fraction (ARF x RF) of 0.001. This assessment was based on assuming 6,000 grams of plutonium melted and that this entire amount is distributed for optimum dispersal (LANL 1996f). The SAR analysis does not make reference to DOE Handbook 3010-94. The SNL SPR-III SAR analysis predates the LANL analysis, and mirrors it in most respects. One notable difference, however, is that the LANL release fraction is five times lower than the SNL release fraction (0.001 versus 0.005).

The source term was quantified for the SWEIS according to DOE Handbook 3010-94 guidance. The MAR is 6,000 grams of weapons-grade plutonium in molten (liquid) form (LANL 1996f). The DR is assessed as 1.0 (all 6,000 grams are molten).

The LPF is not directly calculated or estimated in the TA–18 SAR. Because the SAR assessed no driving force associated with the accident, the release from the kiva was modeled as wind-driven exfiltration. Over a 2-hour period, the release fraction (which is dependent on wind speed) ranges from 0.05 to 0.25 for wind speeds in the range from 1 to 10 miles per second (2.2 to 22.3 miles per hour) (LANL 1996f). Because typical upslope and downslope winds at Los Alamos are in the range of 2.5 to 3 miles (4.0 to 4.8 kilometers) per second (LANL 1990a), DOE has selected an LPF of 0.1 (which is between the values for 2 and 3 miles [3.2 to 4.8 kilometers] per second).

Selection of appropriate ARF and RF values is complicated by the limited description of the accident scenario in the LACEF SAR. The SAR acknowledges the possibility that rupturing the containment vessel could allow molten plutonium to slump to the assembly stand and adjacent areas. For airborne release of particulates from disturbed molten metal surfaces (i.e., flowing metal, actions resulting in continuous surface renewal), DOE Handbook 3010-94 recommends the bounding ARF and RF values of 0.01 and 1.0, respectively (DOE 1994d). The handbook clarifies that the bounding value applies to situations where ignited, molten plutonium is disturbed by direct impact of high air velocities such as during free fall (DOE 1994d).

The handbook also addresses a circumstance involving the airborne release of particulates formed by self-sustained oxidation (molten metal with oxide coat), self-induced convection. The handbook clarifies that this applies to self-sustained oxidation in air of metal pieces (DOE 1994d). The ARF and RF values for this circumstance are 0.0005 and 0.5, respectively.

ARF and RF bounding values for these two sets of circumstances yield initial source terms as follows:

Self-Sustained Oxidation

Source Term = MAR x DR x ARF x RF x LPF

= 6,000 x 1 x 0.0005 x 0.5 x 0.1

= 0.15 grams

Disturbed Molten Metal Surfaces

Source Term = MAR x DR x ARF x RF x LPF

= 6,000 x 1 x 0.01 x 1 x 0.1

= 6.0 grams

The suspension source-term calculation was also performed according to DOE Handbook 3010-94 guidance:

Suspension Source Term = MAR x DR x ARR/hr x 24 hrs x RF x LPF

= 6,000 x 1 x 0.00004 x 24 hrs x 1 x 0.1

= 0.6 grams

The ARR and RF values are based on powder located inside a building with ambient conditions (DOE 1994d). This was considered to be appropriate because the melted plutonium released from the containment device will burn on contact with air and change the physical state of the plutonium.

In addition to the plutonium source term from the melting event, a radiological release will occur as a result of the generation of fission products due to the neutron pulse. The large majority of fission products have very short half-lives (on the order of 0.21 seconds to 3.15 minutes) and their mode of decay is primarily by beta and gamma emission. The SAR analysis assigned an average dose-rate conversion factor for air immersion (cloudshine) of 4,000 millirem-cubic meter per microcurie per year to those beta-gamma emitting radionuclides not having documented values. Comparison of the decay product quantities and dose conversion factors with the plutonium source term values indicated that the fission products provide a negligible contribution to the total dose from internal exposure pathways. Consequently, doses resulting from internal exposure pathways for fission products were not modeled. Doses resulting from the external exposure pathway (air immersion) for fission products (6.02×10^3 curies) were estimated using the SAR-determined average dose-rate conversion factor of 4,000 millirem-cubic meter per microcurie per year.

The accident does not change across the alternatives. The No Action Alternative source term applies to all of the SWEIS alternatives.

Uncertainties and Sensitivities Affecting the Source Term for RAD–13

The source term for RAD–13 is very sensitive to the accident progression, which has unfortunately not been evaluated in detail past the point where the plutonium melts. If the accident progression is relatively benign (involving low pressure melting of the container and candling of the molten liquid down the sides of the Skua device), then the SAR source term is probably conservative. If, however, a more energetic surface reaction occurs in the molten material, then the SAR estimate of the source term is possibly too low.

One uncertainty in this case would be how much of the plutonium would actually be ejected, versus the amount that would cool and freeze to the interior surface of the container. Finely divided liquid plutonium metal at high temperature would be expected to be energetically pyrophoric with the air inside the kiva. The rate of oxidation of plutonium is dependent on: (1) temperature, (2) the surface area of the reacting metal, (3) the oxygen concentration, (4) the concentration of moisture and other vapors in the air, (5) the type and extent of alloying, and (6) the presence of a protective oxide layer on the metal surface (DOE 1994d). Factors 1 and 2 are maximized under the conditions hypothesized; indeed, the plutonium would initially be far above the ignition temperature (i.e., 2,000°F [1,093°C] at release versus the ignition temperature of 914°F to 932°F [490 to 500°C]). Factor 3 is essentially unlimited because oxygen in the air would be replenished from outside the kiva. Factor 6 is not applicable because the plutonium is in a liquid form. The source term from this configuration could be significantly higher than calculated above.

Consequences of RAD–13 for Facility Workers and the Public

Consequences for facility workers and the public are discussed separately. The Kiva #3 control room is located 669 feet (204 meters) from the kiva (LANL 1996f). The walls of the control room are such that 40 percent attenuation of gamma doses from the outside is accomplished (LANL 1996f). In the event of an accident, ventilation systems for the control building (TA–18–30) would be secured. Air exchange with the outside would be a function of wind loading and diffusion in and around wall and ceiling penetrations (LANL 1996f). However, the ventilation system for the control building is not protected by HEPA filters (LANL 1996f).

No acute fatalities are predicted to result from the postulated accident. The mean collective population dose is projected to total 160 person-rem (TEDE), resulting in 0.082 excess LCFs. The public consequences for RAD–13 are provided in Table G.5.6.13–1, which summarizes the modeling results for RAD–13. Mean projected doses for MEIs (and their associated locations) and ground contamination levels are presented in Tables G.5.6.13–2 and G.5.6.13–3, respectively.

G.5.6.14 *RAD–14, Plutonium Release Due to Ion-Exchange Column Thermal Excursion*

General Scenario Description

This accident scenario involves the release of plutonium through the building ventilation systems during a process event. In TA–55, ion exchange columns, inside of gloveboxes, are used to separate out different plutonium compounds. As plutonium nitrate solutions are introduced into these columns, an abnormal increase in temperature is possible. This temperature rise could be due to degraded resin, greater reactivity of the solution with the column resin, or even a limited glovebox fire.

For the accident to proceed, the column must rupture due to a pressure build up caused by the temperature rise. Aerosolized plutonium nitrate could then enter the glovebox and be drawn into the glovebox ventilation system. For any release of material into the building ventilation systems, the glovebox HEPA filter system would have to fail. For the material to reach the environment, the building HEPA filters would also have to fail. This scenario has a probability that is extremely low. The probability is low enough to be deemed incredible even though an initiating event is considered possible.

The accident would have to start from some initiating event such as: (1) inadvertent introduction of a high temperature solution causing the resins to decompose; (2) inadvertent introduction of impurities in the feed stock, such as strong oxidants; and (3) inadvertent introduction of high concentrations of nitric acid. Each of these situations, could set up a reaction in the column that quickly heats the material in the column, possibly leading to an ion-exchange column overpressurization.

Because such situations have occurred, LANL uses resins that are resistive to degradation. The vinyl pyridine polymers used in the ion exchange columns are significantly more resistant than resins incorporating a polymer of polystyrene and divinyl benzene. These resins have a marked improvement in stability for conditions of high temperature, concentrated nitric acid exposure and for conditions of high radiation. Progressive resin deterioration can be detected by decreased resin exchange capacity and the appearance of bead fragments in the effluent. The resins generally are replaced before they become seriously degraded. Even with these precautions, however, problems with resins are known to occur.

TABLE G.5.6.13–1.—*Summary Results for Scenario RAD–13*

ALTERNATIVE	ACCIDENT FREQUENCY	SOURCE TERM AND CONSEQUENCES
No Action	1.6×10^{-5}	Bounding, 6 grams of weapons-grade plutonium initial release, 0.6 grams of weapons-grade plutonium in suspension release over 24 hours; integrated population exposure of 160 person-rem, 0.08 excess LCFs.
Expanded Operations	1.6×10^{-5}	Same as No Action Alternative.
Reduced Operations	1.6×10^{-5}	Same as No Action Alternative.
Greener	1.6×10^{-5}	Same as No Action Alternative.

Special Population Distance: San Ildefonso Pueblo (14,600 m)	1.2×10^{-2}

[a] Approximated at 50 m.

TABLE G.5.6.13–3.—*Predicted Mean Ground Contamination Levels for Scenario RAD–13*

RADIAL DISTANCE	PLUTONIUM-239 GROUND CONCENTRATION (BQ/m^2)
0.0 to 1.0 km	2.6×10^{4}
1.0 to 2.0 km	3.5×10^{3}
2.0 to 3.0 km	1.4×10^{3}
3.0 to 4.0 km	7.1×10^{2}
4.0 to 8.0 km	2.5×10^{2}
8.0 to 12.0 km	9.4×10^{1}
12.0 to 20.0 km	3.7×10^{1}
20.0 to 30.0 km	1.5×10^{1}
30.0 to 40.0 km	8.3×10^{0}
40.0 to 60.0 km	4.4×10^{0}
60.0 to 80.0 km	2.7×10^{0}

BQ/m^2 = Becquerel per square meter

For the accident to proceed, the pressure must buildup and cause a column rupture. Because the pressure can be relieved by either the pressure relief valve or through the output line on the column, both of these components have to fail. In other words, the pressure relief valve does not actuate and the output line on the column is blocked.

At this point in the progression, an accident has occurred; but the material is still contained in the glovebox. For the material to escape the glovebox, the HEPA filter system would have to fail, allowing material into the building ventilation system. For this accident sequence, the HEPA filter is assumed to be damaged by the rupture of the ion-exchange column. Material is then transported by the ventilation system to the building HEPA filters. Again, for this material to escape the building, the multi-staged HEPA filters on the building would have to fail. The material would now be available for atmospheric transport from the south exhaust stack.

This accident progression is used to estimate the frequency of the event. Because there are a number of barriers that must fail, the calculated accident frequency is below the screening criteria cutoffs for credible accidents. The accident has been retained, however, to illustrate the nature of defense-in-depth and how it is used to reduce the frequency and consequences of possible plutonium releases at TA–55.

Comparison of Accident Analysis in the Pit Disassembly and Conversion Demonstration Environmental Assessment and This SWEIS

DOE is preparing an EA (DOE 1998) to examine the environmental impacts of the proposed development and demonstration of an integrated pit disassembly and conversion process for fissile material disposition. The hazard analysis, used for this EA first considered a baseline of public impacts given the hypothetical case where no controls exist for the operation. This evaluation determined that without controls the impacts to the MEI are below the DOE evaluation guidelines. The hazard analysis further quantified the expected consequences to the public, given that the building is designed to provide containment of hazardous material in the event of an accident. Given these controls, the dose to the MEI was reduced to 3 x 10^{-8} rem and the frequency of occurrence was reduced from 10^{-3} to 10^{-5}.

Although the consequence and frequency numbers in the EA are slightly higher than those given for this accident, i.e., in the ion-exchange column thermal excursion, the risks from the pit disassembly and conversion process are considered to fall within the envelop as established by this SWEIS. Additional control barriers, other than those outlined in the EA, exist to further reduce the frequency of an initiating event and to reduce the frequency of an event with public impacts to below the 10^{-6} screening criteria. The consequences for an unconfined release of plutonium are similar and, when taking credit for HEPA filtration, the doses become very low. Doses in this range (considering filtration) could not be distinguished from background doses. Overall, for process events, the risks from this operation would be dominated by the risks of a fire for the CMR Building.

The characterization of risk at LANL, as presented by the set of accidents in this appendix is appropriate, given consideration of the EA analysis. When considering the accident risk associated with the pit disassembly and conversion process for fissile material disposition, the risk profile for LANL (as presented for each alternative) would not change. The SWEIS risk characterization is more realistic because it includes other processes implemented through adherence to DOE safety programs, including the defense-in-depth policy.

No Action Alternative Frequency Analysis

Table G.5.6.14–1 associates the accident progression, as discussed above, with either a frequency of occurrence or a rate of failure. The terms in the table are explained in subsequent sections.

Initiator

There are several types of events that could cause a column overpressurization or rupture. Unfortunately, it is difficult to quantify the initiating event likelihood and therefore the likelihood of the overall accident. A search was done for recorded cases of column overpressurizations or ruptures. This search did not find any cited incidents. To put a bound on this initiator frequency, the ORPS database, where such incidents are systematically cataloged, was used. The last 5 years of data was considered representative of the likely initiators at LANL. No ion-exchange column overpressurization or rupture were reported in the last 5 years. Given that LANL is operated for approximately 260 days per year, the frequency of occurrence is less than 1 event in 1,300 days, or a rate of less than 8×10^{-4} per day. Because there are essentially 260 operating days per year, the annual frequency for a column rupture is 0.2 per year (260 operating days per year x 8×10^{-4} per day). This number, although very conservative, was used as the likelihood that precursors exist for these process type accidents. Precursors would include having contaminants in the solutions, degraded resins, etc.

Human Error Probability

Missed Procedural Step. Procedures are used to ensure that the setups are correct and materials introduced into the process meet the specified criteria, such as concentrations for solutions, etc. If one of these steps is omitted, then the initiating event can progress into an accident (e.g., overpressurization of an ion-exchange column). Generally, it takes more than one step to be missed or improperly done in order for an accident to progress; but, in this case it is assumed that the omission of one step, such as a quality control step for measuring the concentration of feed material, occurs and can contribute to the overpressurization event occurring. The probability for omitting a step in a procedure is generally from 3×10^{-4} to 3×10^{-3} per demand (Mahn et al. 1995). Therefore, the midpoint of 1.7×10^{-3} per demand is used in this analysis.

Missed Procedural Check. Because the setups and the processes are governed by procedures, checks are also made by operations staff to ensure that each step has been followed. The failure of an operations staff member to detect such an omission is 0.1 per demand (Swain and Guttmann 1983).

Process Controls

Blocked Output Line. Pressure can bleed out of the ion-exchange column through the output line. However, it has been assumed that this output line, under this condition, can easily become blocked. Therefore, the probability of this line failing to relieve overpressurization is assumed to be 1.0, a very conservative assumption.

Relief Valve Failure. Based on industry experience, the failure rate for relief valves is from 1.4×10^{-5} to 3.6×10^{-5} per demand (NRC 1998, Table III 2-3). Again, the midpoint value of 2.5×10^{-5} was selected for this analysis.

HEPA Filter (Glovebox). The glovebox has a HEPA filter to contain any material that could become aerosolized in the glovebox. Although, the overpressurization and subsequent rupture of a column is not expected to damage the glovebox. This analysis conservatively assumes that the HEPA filter fails, and the probability is set to 1.0

TABLE G.5.6.14–1.—*Accident Progression Associated with Either Occurrence Frequency or Failure Rate*

SCENARIO PROCESS EVENT AT TA–55	INITIATOR FREQUENCY	HUMAN ERROR PROBABILITY		PROCESS CONTROL FAILURE		BUILDING CONTROL FAILURES	FREQUENCY OF ION-EXCHANGE COLUMN OVER-PRESSURIZATION AND PLUTONIUM RELEASE
		MISSED PROCEDURAL STEP	MISSED PROCEDURAL CHECK	PROBABILITY OF BLOCKED LINE	PROBABILITY OF RELIEF VALVE FAILURE		
Ion-Exchange Column Rupture	0.2/yr	0.0017	0.1	1.0	2.5×10^{-5}	1.0 (glovebox HEPA filter failure)	8.5×10^{-10}/yr (worker hazard only)
Ion-Exchange Column Rupture and Loss of HEPA Filters	0.2/yr	0.0017	0.1	1.0	2.5×10^{-5}	6.3×10^{-7} (HEPA failure/HVAC operating)	5.6×10^{-16}/yr
Ion-Exchange Column Rupture and Loss of Ventilation System	0.2/yr	0.0017	0.1	1.0	2.5×10^{-5}	4.5×10^{-7} (HEPAs operating/HVAC fails)	3.8×10^{-16}/yr

Building Controls

HEPA System. For TA–55, filtration consists of a three-stage HEPA filter system located on the outside of the facility. Any incident inside of the facility, such as an ion-exchange column rupture, would not damage the HEPA filters or the ventilation system. Therefore, for the HEPA filters to fail, at the same time this accident occurs, is an independent event.

LANL data from 1990 to 1994 (LANL 1990b, LANL 1991b, LANL 1994c, LANL 1994d, and LANL 1995h) looked at the failure rates of HEPA filters. When the failure rate of a two-stage HEPA filter system was considered (LANL 1996k), the failure probability for a single HEPA stage was 5 percent. For three stages of filters to fail, the failure probability is 1.3×10^{-4}.

HEPA System Summary

- *1st stage HEPA filter failure: 0.05 per demand*
- *2nd stage HEPA filter failure: 0.05 per demand*
- *3rd stage HEPA filter failure: 0.05 per demand*
- *Monitoring instrumentation failure: 5×10^{-3} per demand*
- *Failure of three-stage HEPA filter system: 6.3×10^{-7} per demand*

However, the HEPA filters on TA–55 are monitored to make sure they are functioning properly. The difference in pressure across the filter banks is monitored. An alarm sounds if the proper pressure drops are not being maintained. Also, the sensor is covered by a preventive maintenance program and administrative procedures. Given these conditions, the probability of the sensor failing is 5×10^{-3} (Mahn et al. 1995).

HEPA System Human Error Probability. Given that the HEPA systems are monitored and action is required to make sure the HEPA filters are operating properly, it is always possible for operators to fail to respond. The Human Reliability Handbook identifies a basic HEP for these circumstances as 0.025 per demand (Swain and Guttmann 1983). A shift supervisory function would also be staffed and would be expected to respond if the operator does not. The HEP for this function is 0.1 (Swain and Guttmann 1983). The total HEP for H_{HVAC} is 0.025 x 0.1, or 2.5×10^{-3} per demand. If this probability is coupled with the probability that the HEPA filters could fail, the probability that the building would be operating without containment is 1.6×10^{-10}.

Facility Containment. If the ventilation system fails (i.e., the fans fail), during the rupture of the ion-exchange column, the negative pressure is not maintained between the room and the glovebox and between the laboratory and the environment. Under these conditions, the building is said to go into a breathing mode and unfiltered air can be exchanged between the building and the outside air. However, because there is nothing keeping the material airborne or drawing it outdoors, very little material can escape.

Facility Containment

- *Probability of loss of power: 1.5×10^{-4}*
- *Probability of diesel generator failure: 0.03*
- *Common mode beta factor: 0.1*
- *Probability of ventilation system failure: 4.5×10^{-7}*

For the building to go into a breathing mode, the power to the fans would have to fail and the back-up diesel generator would have to fail also. The annual rate for loss of power is 0.04 per year according to the Western Systems Coordination Council (Oswald et al. 1982). A typical beta factor for common mode failures is 0.1 (Fleming et al. 1985).

Expanded Operations, Reduced Operations, and Greener Alternatives Frequency Analysis

This accident covers the generic operation of TA–55 for process type events. No increase or decrease in the level of activity associated with the accident frequency is anticipated for any of the other alternatives.

No Action Alternative Source and Suspension Term Calculations

Source Term with Operational HEPA and HVAC Systems. Table G.5.6.14–2 summarizes the results of the source term calculations. The derivation of these numbers is described in the following sections.

When the accident occurs, plutonium is either in the form of plutonium nitrate in solution or it has adhered to the column resin. When the column ruptures, the plutonium can be aerosolized either by the flashing of the solution or by the burning of the resin bed. Because these represent two different mechanisms for plutonium release from the ion-column rupture, the two source terms are tracked separately.

Material-at-Risk. For the solution, MAR equals 246 grams in the form of plutonium nitrate. The maximum concentration of the solution is 100 grams per liter. The volume of the column is 2.46 liters; therefore, the MAR is 246 grams of weapons-grade plutonium in solution as plutonium nitrate.

Material-at-Risk

- *Material Source: Plutonium Nitrate*
- *MAR = 246 g*
- *Material Source: Plutonium Oxide*
- *MAR = 1,000 g*

For the column, the maximum capacity of the resin is 1,000 grams of weapons-grade plutonium (LANL 1996k). Although the plutonium on the resin is not in oxide form, the plutonium released during the accident is assumed to be oxidized due to the high temperatures associated with the burning of the column resins. The oxide designation is used here for tracking purposes only.

Damage Ratio. For flashing of the solution, DR is assumed to be 1.0. All the material in the solution is considered to be involved in the accident.

Damage Ratio

- *Material Source: Plutonium Nitrate*
- *DR = 1.0*
- *Material Source: Plutonium Oxide*
- *DR = 0.1*

Although the resins have remained stable under high temperature and exposure to radiation, 10 percent of the resin in the column is assumed to burn or degrade due to the high temperatures. This assumption is a conservative estimate of the material on the column that can be released during the accident.

TABLE G.5.6.14–2.—*Source Term with Operational HEPA and HVAC Systems*

MATERIAL SOURCE	MAR	DR	ARF	RF	LPF	SOURCE TERM
Plutonium Nitrate	246 g	1.0	0.01	0.6	8×10^{-9}	1.2×10^{-8} g
Plutonium Oxide	1,000 g	0.1	0.01	1.0	8×10^{-9}	7.2×10^{-9} g

Airborne Release Fraction and Respirable Fraction. For the solution, the bounding values were for a flashing spray from relatively low energy liquids. The liquids had temperatures greater than the boiling point but less than 122°F (50°C) superheat. Therefore, the values for the ARF and RF are 0.01 and 0.6, respectively (DOE 1994d).

Airborne Release Fraction (ARF) and Respirable Fraction (RF)

- *Material Source: Plutonium Nitrate*
  - *ARF = 0.01*
  - *RF = 0.6*
- *Material Source: Plutonium Oxide*
  - *ARF = 0.01*
  - *RF = 0.9*

In the TA–55 SAR (LANL 1996k), the product of the ARF x RF is given as 0.009. This product is consistent with the highest measured ARF of 0.0078, with an RF of 0.9, for the burning of contaminated polystyrene and ion-exchange resin (DOE 1994d). Therefore, an ARF x RF of 0.009 was used in this analysis.

Leak Path Factor. For this case, the material escapes into the ventilation system and is filtered through a three-stage HEPA filter. The filteration factor is 8 x 10^{-9} (LANL1996k).

Leak Path Factor (LPF)

- *Material Source: Plutonium Nitrate*
  - *LPF = 8 x 10^{-9}*
- *Material Source: Plutonium Oxide*
  - *LPF = 8 x 10^{-9}*

Suspension Term with Operational HEPA and HVAC Systems. Table G.5.6.14–3 summarizes the results of the suspension term calculations. The amount of suspended material is based on the type of accident and resulting dispersal mechanisms after the accident. For this case, the HEPA filters and ventilation systems are assumed to be operational. Each of the terms is explained in the following sections.

Material-at-Risk. Because very little material escapes to the environment, the amount of material assumed to remain at the site for further dispersal is the same as the original MAR.

Material-at-Risk

- *Material Source: Plutonium Nitrate*
  - *MAR = 246 g*
- *Material Source: Plutonium Oxide*
  - *MAR = 1,000 g*

Damage Ratio. In both instances, the same fraction of material is considered available for further dispersal as was available for the original accident. All the material in solution is considered available. Plutonium that was not released from the resin bed initially is still not considered available; therefore, the DR is 10 percent, or 0.1.

Airborne Release Rate, Release Period, and Respirable Fraction. For the solution, the suspended material is assumed to come from a liquid on a heterogeneous surface (stainless steel, concrete) exposed to low air speeds up to

TABLE G.5.6.14–3.—*Suspension Term with Operational HEPA and HVAC Systems*

MATERIAL SOURCE	MAR	DR	ARR	RELEASE PERIOD	RF	LPF	SUSPENSION TERM
Plutonium Nitrate	246 g	1.0	4 x 10^{-7}/hr	24 hrs	1.0	4 x 10^{-9}	1.9 x 10^{-11} g
Plutonium Oxide	1,000 g	0.1	4 x 10^{-5}/hr	24 hrs	1.0	4 x 10^{-9}	7.7 x 10^{-10} g

Damage Ratio

- *Material Source: Plutonium Nitrate*
  - *DR = 1.0*
- *Material Source: Plutonium Oxide*
  - *DR = 0.1*

normal facility ventilation flow (DOE 1994d). These values are bounding values for the type of suspension that could have been considered. Thus, the ARR and RF selected were 4 x 10^{-7} and 1.0, respectively. Although, the release period is assumed to be 24 hours, this is considered a very conservative value given the limited extent of the accident.

Airborne Release Rate, Release Period, and Respirable Fraction

- *Material Source: Plutonium Nitrate*
  - *ARR = 4 x 10^{-7} per hour*
  - *Release Period = 24 hours*
  - *RF = 1.0*
- *Material Source: Plutonium Oxide*
  - *ARR = 4 x 10^{-5} per hour*
  - *Release Period = 24 hours*
  - *RF = 1.0*

For the plutonium released from the resin bed, it is assumed that the material was deposited out on material in the glovebox. The values selected for the ARR and RF, 4 x 10^{-5} and 1.0, were for surface contamination from combustible solids under ambient conditions (DOE 1994d). Again these values along with the release period of 24 hours were bounding given this type of accident.

Leak Path Factor. The HEPA filters and the ventilation system is assumed to be operating after the accident for this scenario. Thus, the filteration efficiency for the three-stage HEPA filters is used in this case, and very little of the material can escape.

Leak Path Factor

- *Material Source: Plutonium Nitrate*
  - *LPF = 8 x 10^{-9}*
- *Material Source: Plutonium Oxide*
  - *LPF = 8 x 10^{-9}*

Source Term with Failed HEPA Filters and Operational HVAC Systems. Table G.5.6.14–4 summarizes the results of the source term calculations. The values are the same for the accident with operational HEPA and HVAC systems, except for LPF. Therefore, only LPF is discussed below.

Leak Path Factor. For this case the HEPA filters are assumed to fail, but the ventilation system is operating. Material is drawn into the ventilation system and released out the south stack of the building. No credit is assumed either for settling or deposition in the ductwork, etc.; therefore, the LPF is 1.0.

Leak Path Factor

- *Material Source: Plutonium Nitrate*
  - *LPF = 1.0*
- *Material Source: Plutonium Oxide*
  - *LPF = 1.0*

Suspension Term with Failed HEPA Filters and Operational HVAC System. Table G.5.6.14–5 summarizes the results of the suspension term calculations. The material suspended is based on the type of accident and resulting dispersal mechanisms after the accident. For this case, the HEPA filters have failed but the fans are assumed to be operational. These terms are identical to the case where the HEPA filters have not failed, except for MAR and LPF. Therefore, only MAR and LPF are discussed below.

Material-at-Risk. The amount of material remaining at the site is assumed to be the initial

TABLE G.5.6.14–4.—*Source Term with Failed HEPA Filters and Operational HVAC Systems*

MATERIAL SOURCE	MAR	DR	ARF	RF	LPF	SOURCE TERM
Plutonium Nitrate	246 g	1.0	0.01	0.6	1.0	1.5 g
Plutonium Oxide	1,000 g	0.1	0.01	0.9	1.0	1.0 g

TABLE G.5.6.14–5.—*Suspension Term with Failed HEPA Filters and Operational HVAC Systems*

MATERIAL SOURCE	MAR	DR	ARR	RELEASE PERIOD	RF	LPF	SUSPENSION TERM
Plutonium Nitrate	244.5 g	1.0	4×10^{-7}/hr	24 hrs	1.0	1.0	0.0023 g
Plutonium Oxide	999.2 g	0.1	4×10^{-5}/hr	24 hrs	0.9	1.0	0.096 g

MAR, minus the amount that was released for atmospheric transport.

> ***Material-at-Risk***
>
> - *Material Source: Plutonium Nitrate*
>   - *— MAR = 246 g*
>   - *— Dispersed MAR = 1.5 g*
>   - *— Suspension MAR = 244.5 g*
> - *Material Source: Plutonium Oxide*
>   - *— MAR = 1,000 g*
>   - *— Dispersed MAR = 0.81 g*
>   - *— Suspension MAR = 999.2 g*

Leak Path Factor. For this case, the HEPA filters are assumed to fail but the ventilation system is operating. Material is drawn into the ventilation system and released out the south stack of the building. No credit is assumed either for settling or deposition in the ductwork, etc. The LPF is taken as 1.0.

> ***Leak Path Factor***
>
> - *Material Source: Plutonium Nitrate*
>   - *— LPF = 1.0*
> - *Material Source: Plutonium Oxide*
>   - *— LPF = 1.0*

Source Term with Failed HVAC Fans and Operational HEPA Filters. Table G.5.6.14–6 summarizes the results of the source term calculations. The accident progression is the same except that, in this case, the HEPA filters remain in tact but the fans, drawing material through the ventilation systems, fail. The only way to get material out of the building is through exchange of air with the atmosphere, such as entering or exiting the building. Thus, the only term that is discussed below is LPF.

Leak Path Factor. This LPF is for a building in a breathing mode, but with a strong temperature difference between the facility and the environment. This value is generally associated with a fire. Although a fire is not part of this accident progression, the value will be used here as a conservative number.

> ***Leak Path Factor***
>
> - *Material Source: Plutonium Nitrate*
>   - *— LPF = 0.011*
> - *Material Source: Plutonium Oxide*
>   - *— LPF = 0.011*

Suspension Term with Failed HVAC Fans and Operational HEPA Filters. Table G.5.6.14–7 summarizes the results of the suspension term calculations. The material suspended is based on the type of accident and resulting dispersal mechanisms after the accident. For this case, the HVAC fans have failed but the HEPA filters remain intact. These terms are identical to the case where the HEPA filters failed, except for LPF. Because so little material is released during the accident, MAR is considered the same as the source term MAR. Therefore, only LPF is discussed below.

Leak Path Factor. The value will be used as a conservative number and is the same LPF used in the determination of the source term.

> ***Leak Path Factor***
>
> - *Material Source: Plutonium Nitrate*
>   - *— LPF = 0.011*
> - *Material Source: Plutonium Oxide*
>   - *— LPF = 0.011*

Summary of Source and Suspension Terms. Table G.5.6.14–8 summarizes the amount of material that is available for atmospheric transport. Each case represents a different failure mechanism for the building HEPA filtration systems.

Consequences for Facility Workers. All facility operations personnel receive emergency preparedness training specific to the facility and for procedures applicable to the entire LANL.

TABLE G.5.6.14–6.—*Source Term with Failed HVAC Fans and Operational HEPA Filters*

The Emergency Action Plan directs personnel to move as quickly as possible away from any hazardous situation and to make appropriate notifications to the EM&R Office as soon as they are safely away from the hazard. Once notified, the EM&R Office assumes all elements of emergency response and coordination.

Breach of the ion-exchange column may include breach of adjacent vessels, breach of the glovebox exhaust filter, and damage to one or more gloves and/or loss of a window in the proximity of the affected column. The dissipation of the pressure surge through the glovebox line and the glovebox ventilation exhaust is such that no damage to the glovebox exhaust filter plenums would occur. If an operations technician is involved in glovebox work at the time of the postulated accident, severe injury is possible. The worker would be exposed to some glass shrapnel (protected, for the most part, by the shielding screen on the column) and to the forcibly ejected nitric acid/ plutonium nitrate solution (LANL 1996k).

No fatalities have been associated with ion-exchange resin explosions in nuclear applications. One medical disability resulted from the Hanford cation exchange column incident.

The airborne plutonium concentration in the room will be a function of the volume of gas generated by the column rupture, the degree of mixing in the glovebox, the level of damage to the glovebox, and the resultant volume of gas released to the room. Worker exposure is dependent on worker proximity to a potential glovebox breach and the residence time in the aerosol cloud. If glovebox confinement is breached, the room's continuous air monitor would detect the release of radioactive material to the room and provide both local and TA–55 Operation Center alarm of the incident.

Consequences for the Public. MACCS was used to determine the doses for the integrated populations. There is only one scenario where the HEPA filters failed and the fans continued to draw material through the ventilation system. Therefore, the atmospheric transport was modeled as an elevated release for both the initial release and the suspension release. Further discussions of atmospheric modeling can be found in section G.2.4.

As a point of comparison, the results of the MACCS runs were ratioed by the amount of material released in the other cases. Thus, the dose of each scenario can be compared (Table G.5.6.14–9).

From these results, no additional excess fatal cancers are anticipated from this event. Any of these results are well within the variations of measuring cancer fatalities within a population group.

The results of the analysis are summarized in Table G.5.6.14–10. No acute fatalities are predicted to result from the postulated accident. The mean collective population dose is projected to total 130 person-rem (TEDE), resulting in 0.063 excess fatal cancers. Mean projected doses for MEIs (and their associated locations) and ground contamination levels are presented in Tables G.5.6.14–11 and G.5.6.14–12. Note that the MEIs are given only for the highest consequence result, but the resultant doses would be lower than those presented.

Deposition Profile. This result is given only for the scenario with the highest consequences. For the other cases the result is expected to be less.

G.5.6.15 *RAD–15, Plutonium Release from Laboratory and Wing Fires at CMR*

General Scenario Description

The accident scenario discussed in RAD–15 is for a general process-initiated fire at the CMR

TABLE G.5.6.14–9.—*A Result Comparison of the MACCS Runs*

	TOTAL MATERIAL RELEASED	INTEGRATED POPULATION DOSE (PERSON-REM)	EXCESS FATAL CANCERS
Release with Filtration System Operating	2.0×10^{-8} g	1.0×10^{-6}	5×10^{-10}
Release with HEPA Failed	2.4 g	130	0.06
Release with HVAC Failed	0.14 g	7.0	0.0035

TABLE G.5.6.14–10.—*Summary Results for RAD–14*

Building. The fire is postulated to start in a laboratory that in the future may house a plutonium hydride-dehydride process. A variation of the scenario in which the fire develops into a wing-wide fire is also analyzed.

The plutonium hydride-dehydride process was developed from a small-scale experimental setup located at TA–55–4. This experiment was used to determine the rates of reaction and other physical parameters that were necessary for a feasibility study as well as the design of the hydride-dehydride process. In the future, the process may involve up to 4.5 kilograms of plutonium, and so was selected for analysis.

The fire is assumed to start from any one of a number of possible initiators. The fire is not put out either by personnel in the laboratory with manual fire extinguishers or by the laboratory automatic fire suppression systems. Furthermore, doors to the laboratory are left open allowing aerosolized plutonium to get into the corridor of the wing. Finally, emergency doors are used by personnel to exit the CMR Building, creating a pathway for aerosolized plutonium to escape the building.

In the future, this hydride-dehydride process may be located at both TA–55–4 and at the CMR Building. This scenario at TA–55–4 is not considered because the dehydride-hydride process itself is not considered a potential fire initiator due to current design features, which are listed in the preconceptual design report (LANL 1996q). Secondly, the fire history at TA–55–4 does not support a general fire scenario, given the defense-in-depth building features (such as fire barriers and HEPA filters), and the process designs (such as process monitoring and limited combustible material).

No Action Alternative Frequency Analysis

The frequencies above are derived in the subsequent subsections.

No Action Alternative Frequency Analysis

- *CMR Scenario: Laboratory Fire*
  - — *Fire Frequency = 4.0×10^{-3}*
  - — *Plutonium Release Frequency = 3.6×10^{-5}*
- *CMR Scenario: Wing-Wide Fire*
  - — *Fire Frequency = 3.5×10^{-5}*
  - — *Plutonium Release Frequency = 3.2×10^{-5}*

Fire Initiators

No specific initiator is used for this accident sequence. Instead, fires are taken to occur at a rate of approximately one per year. This frequency is based on a review of the number of CMR incident reports found in the ORPS database. There were three reported fire incidents in the 5 years.

Fire Frequency

Damage to the plutonium is possible only if fire suppression fails. Fire suppression includes actions by personnel in the laboratory as well as automatic fire suppression systems. Therefore, the frequency of a laboratory fire is the product of the frequency of fire incidents and the probability that successive fire suppression systems will fail. If either of these barriers succeed, the result is a fire that does not release radioactive material.

Fire Frequency

- *Frequency of fire incidents at CMR 1 per year*
- *Probability of manual suppression failure: 0.1 per event*
- *Probability of automatic suppression failure: 0.04 per event*
- *Frequency of laboratory fires at CMR 4×10^{-3} per year*

Operating history for industry indicates that about 90 percent of fires are manually extinguished. The same probability for the manual suppression of fires is used for accident analysis at the CMR Building (LANL 1997a). Thus, the second term is given as 0.1. The third term is taken from the probability of failure of the fire suppression system at TA–55 (SNL 1990).

For a wing-wide fire, there must first be a laboratory fire, and then a failure of the laboratory fire barriers. The fire barriers are the walls and doors of the laboratory. The frequency of a wing-wide fire is therefore estimated to be 3.5×10^{-5} per year. If the walls and doors contain the fire, no wing-wide fire occurs.

The fire door is a Type 1 barrier with a failure rate of 0.0074 per demand. The walls are a Type 3 barrier with a failure rate of 0.0012. Because either the door or walls could fail and therefore permit the fire to propagate into the wing, the sum of these terms, 0.0086, is the probability a fire barrier will fail.

Fire Frequency (Wing Wide)

- *Frequency of fire incidents at CMR 1 per year*
- *Probability of manual suppression failure: 0.1 per event*
- *Probability of laboratory automatic suppression failure: 0.04 per event*
- *Probability of laboratory fire barrier failure: 0.0086 per demand*
- *Estimated frequency of wing fires at CMR: 3.5×10^{-5} per year*

Failure of Containment and Release of Plutonium

Laboratory Fire. For the laboratory fire, in order for a substantial quantity of material to be released to the environment, the material must have a direct exit to the environment. If the material escape path is through the HEPA filters that filter exhaust air from the laboratory, or through those HEPA filters that separately process exhaust air from the wing, the material will be essentially contained on the filters. The failure rate of HEPA filters is approximately 1.3×10^{-5}. Thus, the combination of a fire and HEPA filter failure (3.5×10^{-5} per year x 1.3×10^{-5}) is not a reasonably foreseeable event.

Other means of allowing material to escape to the environment include creating openings into the laboratory that allow material to escape. For the laboratory fire, this includes leaving doors open or allowing material to escape through openings in the doors. In addition, because the laboratories are contained within the wing, a second opening from the wing to the outside must be created, such as by leaving an emergency exit open. That is, the material must escape a laboratory into the wing, and then escape the wing into the outdoors. The joint probability of a release is illustrated as follows:

> ***Laboratory Fire***
>
> - *Frequency of laboratory fires at CMR: 0.0004 per year*
> - *Probability of laboratory containment failure: 0.9 per event*
> - *Probability of wing containment failure: 0.1 per event*
> - *Frequency of plutonium release: 3.6 x 10^{-5} per year*

During a laboratory fire, it is considered quite probable that doors would be left open to accommodate personnel exiting the laboratory, or be opened for fire fighting equipment. Thus, the second term is conservatively estimated to be 0.9.

During a laboratory fire, personnel also may use wing emergency exits. The probability that these doors will not close is only 0.01 (LANL 1997a).

Wing Fire. For the wing fire, the frequency of releasing material is the joint frequency of a wing fire and the loss of confinement of material by the wing. This is illustrated as follows:

> ***Wing Fire***
>
> - *Frequency of wing fires at CMR: 3.5 x 10^{-5} per year*
> - *Probability of wing containment failure 0.9 per event*
> - *Frequency of plutonium release: 3.2 x 10^{-5} per year*

During a wing-wide fire it is considered quite probable that the confinement for the wing will be lost. Thus, the second term is determined to be 0.9.

Expanded Operations, Reduced Operations, and Greener Alternatives Frequency Analysis. The fire frequencies at the CMR Building remain the same across the alternatives. Due to process design features, the introduction of the hydride-dehydride process does not change the fire frequency at the CMR Building.

Uncertainties and Sensitivities Affecting the Frequency of RAD–15

The initiating fire frequency selected was that of all fires. The fact that these fires require a significant combustible loading to enable small fires to spread to the point of involving an entire laboratory and then a wing is not addressed. It is a recognized policy, enforced in practice and procedures, and addressed in worker training, to keep unnecessary combustibles out of areas where there is plutonium.

No Action Alternative—Initial Source and Suspension Term. Table G.5.6.15–1 summarizes the source term calculations. The derivation of these numbers is described in the following subsections.

The source terms are derived from consideration of the total amount of material that can be involved in a fire. Although fires can involve lesser amounts of material, the risk-dominant scenarios are those that damage

TABLE G.5.6.15–1.—*Summary of the Source Term Calculations (No Action Alternative)*

SCENARIO	MAR	DR	ARF	RF	LPF	SOURCE TERM
Laboratory Fire	1.0 kg	1.0	0.006	0.01	0.23	0.014 g
Wing Fire	6.0 kg	1.0	0.006	0.01	1.0	0.36 g

the entire laboratory or wing, with its the entire material inventory.

Material-at-Risk. MAR is the administrative limit for material in a laboratory (i.e., 1.0 kilogram of plutonium-239 equivalent). For the wing, the administrative limit is 6.0 kilogram plutonium-239 equivalent.

Material-at-Risk

- *Scenario: Laboratory Fire*
  — *MAR = 1.0 kg*
- *Scenario: Wing Fire*
  — *MAR = 6.0 kg*

Damage Ratio. The fire is assumed to damage the entire inventory. Therefore, the DR is assumed to be 1.0.

Damage Ratio

- *Scenario: Laboratory Fire*
  — *DR = 1.0*
- *Scenario: Wing Fire*
  — *DR = 1.0*

Airborne Release Fraction and Respirable Fraction. The ARF and RF values are taken from DOE Handbook 3010-94 and are based on material type, its form, and the nature of the challenge. The inventory is considered to be in a dispersible form. The ARF and RF values are selected for powder, even though not all of the material in the CMR Building is in the form of a powder. Other material forms and release mechanisms could be postulated, and some combinations could lead to higher values of ARF and RF. However, there are no controls in place at the facility that would control the inventories of various forms and packaging to be present. Also, evaluations of the plutonium facility fires at the Rocky Flats Plant demonstrated that the major contributor to environmental releases during those events was the tracking of contamination out of the facility by the firefighters and other responders. Assuming the material to be in powder form results in the maximum amount of material being made available for this release mechanism. For a fire, the recommended ARF and RF values are 0.006 and 0.01, respectively (DOE 1994d).

Airborne Release Fraction and Respirable Fraction

- *Scenario: Laboratory Fire*
  — *ARF = 0.006*
  — *RF = 0.01*
- *Scenario: Wing Fire*
  — *ARF = 0.006*
  — *RF = 0.01*

Leak Path Factor. The laboratory fire does not establish a direct path to the environment. Rather, a laboratory fire that does not propagate to involve the wing has an LPF of 0.23. This is the highest LPF found from complex modeling studies for this facility (LANL 1998a). For the wing-wide fire, loss of containment for the building equates to an LPF of 1.0.

Leak Path Factor

- *Scenario: Laboratory Fire*
  — *LPF = 0.23*
- *Scenario: Wing Fire*
  — *LPF = 1.0*

No Action Alternative—Suspension Term. The suspension term is the amount of material subsequently dispersed from the location of the accident by wind or other disturbances. The amount of material available for suspension is highly dependent on accident response and clean-up activities.

Table G.5.6.15–2 summarizes the suspension term results. It should be noted that if the

TABLE G.5.6.15–2.—*Summary of the Suspension Term Calculations (No Action Alternative)*

SCENARIO	MAR	DR	ARR	RELEASE PERIOD	RF	LPF	SUSPENSION TERM
Laboratory Fire	1.0 kg	1	0.00004	24	1	4×10^{-9}	3.84×10^{-9} g
Wing Fire	6.0 kg	1	0.00004	24	1	1	5.76 g

building remains intact after a wing fire, or if prompt clean-up activities are implemented, this term will be much smaller and could be near zero.

Material-at-Risk. The material remaining at the site is the initial source terms, minus the amount that was initially dispersed in respirable form. Because so little of the initial MAR is transported away from the site by the fire, the amount that is subject to suspension is the same as the initial MAR.

Material-at-Risk

- *Scenario: Laboratory Fire*
  - *— Initial MAR = 1.0 kg*
  - *— Initial Source Term = 0.014 g PE-Ci*
  - *— Suspension MAR = 1.0 kg*
- *Scenario: Wing Fire*
  - *— Initial MAR = 6.0 kg*
  - *— Initial Source Term = 0.36 g PE-Ci*
  - *— Suspension MAR = 6.0 kg*

Damage Ratio. For suspension, the amount of material damaged was considered to be the same as the fraction that was damaged in the fire.

Damage Ratio

- *Scenario: Laboratory Fire*
  - *— DR = 1.0*
- *Scenario: Wing Fire*
  - *— DR = 1.0*

Airborne Release Rate, Release Period, and Respirable Fractions. The ARR and RF selected correspond to a bed of powder exposed to nominal atmospheric conditions, even though this material may remain indoors away from the wind (DOE 1994d). The release period is conservatively assumed to be 24 hours, but could be shorter depending on when clean-up is begun.

Airborne Release Rate, Release Period, and Respirable Fractions

- *Scenario: Laboratory Fire*
  - *— ARR = 0.00004*
  - *— Release Period = 24*
  - *— RF = 1*
- *Scenario: Wing Fire*
  - *— ARR = 0.00004*
  - *— Release Period = 24*
  - *— RF =1*

Leak Path Factor. For a laboratory fire, the ventilation and HEPA filters are considered to be functional. The LPF for HEPA filtration, 4×10^{-9}, is therefore used for the laboratory fire. For a wing fire, the large damage assumed for this event is assumed to produce an LPF of 1.0.

Leak Path Factor

- *Scenario: Laboratory Fire*
  - *— LPF = 4×10^{-9}*
- *Scenario: Wing Fire*
  - *— LPF = 1*

Expanded Operations Alternative—Source and Suspension Term Calculations. For the Expanded Operations Alternative, the hydride-dehydride process could be located at either the

CMR Building or TA–55. As noted earlier, the general fire scenario is not reasonably foreseeable for TA–55. Therefore, the laboratory fire is assumed to be located in the CMR Building. The material for the hydride-dehydride process is considered to be in addition to the material already present in a CMR laboratory and wing.

Table G.5.6.15–3 summarizes the results of the source term determination. Each of the terms is derived in the following sections.

Material-at-Risk (Table G.5.6.15–4). The hydride-dehydride process is the continuous processing of plutonium from a solid to a plutonium hydride and then into a plutonium powder. The maximum amount of plutonium hydride estimated to be in the process is 250 grams. This material is represented separately because of its pyrophoric nature. The remainder of the material in the laboratory is the feedstock for the hydride-dehydride process, 4.25 kilograms of plutonium metal (LANL 1997d). Although the CMR Building has an administrative wing limit of 6 kilograms of plutonium-239 equivalent, for the Expanded Operations Alternative, the amount of material associated with the hydride-dehydride process has been added to the amount currently in a CMR wing.

Damage Ratio (Table G.5.6.15–5). Because the fire is assumed to involve the entire laboratory, the damage ratio is 1.0. Because the wing fire is assumed to damage the entire wing, the damage ratio for the material is again assumed to be 1.0.

Airborne Release Fraction and Respirable Fraction (Table G.5.6.15–6). The ARF and RF values from DOE Handbook 3010-94 are 0.01 and 1.0, respectively, for finely divided plutonium hydride (DOE 1994d).

Leak Path Factor (Table G.5.6.15–7). LPF is taken as 0.23 for the laboratory fire and 1.0 for the wing fire (LANL 1998b).

Expanded Operations Alternative—Suspension Term. Table G.5.6.15–8 summarizes the results for the suspension term.

Material-at-Risk (Table G.5.6.15–9). The material available for suspension after the fire is considered the initial MAR, minus the respirable quantity transported off site. In most instances, except for the plutonium hydride, so little is considered to have be transported away that the initial MAR was used for the suspension MAR.

Damage Ratio (Table G.5.6.15–10). Because of the fire scenario, all material was considered to be vulnerable to further dispersal. The damage ratio is therefore 1.0.

Airborne Release Rate, Release Period, and Respirable Fraction (Table G.5.6.15–11). The ARF and RF values are 4 x 10^{-5} per hour and 1.0 (DOE 1994d). The release period is considered to be 24 hours. Prompt clean-up can reduce this amount considerably.

Leak Path Factor (Table G.5.6.15–12). For a laboratory fire, the ventilation and HEPA filters are considered to be functional. The LPF for HEPA filtration is therefore used for the laboratory fire. For a wing fire, the large damage assumed for this event corresponds to an LPF of 1.0.

Uncertainties and Sensitivities affecting the Source Term for RAD–15. The values calculated above are bounding. The largest uncertainty in the source term is considered to be the assumption of an LPF of 1.0. Such a large LPF may be applicable when the structure has completely failed (i.e., collapsed) or when the structure is intact but the HVAC fans are continuing to run with failed HEPA filters. A running ventilation system will pull air into the building through opened doors. In this conservative analysis, it is assumed that the HVAC system is failed or bypassed, but the structure remains intact.

The assumption also was made that one or a few doors would permit aerosolized material to escape. The area of the doors is small relative to the volume of the building, and so there will be a delay during which airborne material will be depositing within the building during its transit between the fire and the release points. This deposition is not accounted for in this analysis. The amount of material available for release also will be reduced by the foam and water used by fire fighting crews who are supposedly leaving doors open. To assume that fire fighters will have open doors requires the sensible assumption that they also will be laying down suppressants that reduce the initial release and will stop all subsequent suspension.

No Action, Expanded Operations, Reduced Operations, and Greener Alternatives Consequences for Facility Workers

Consequences to Workers. From one to three workers may be present in the glovebox operations. These workers could be injured or killed due to direct fire effects in a laboratory fire, or they could be exposed to plutonium oxide particulates by inhalation.

In the case of a wing fire, there may be several dozen workers present in the wing. These workers could be injured or killed due to direct fire effects, or could be exposed to plutonium oxide particulates by inhalation. Workers elsewhere in the building could be exposed to plutonium inhalation and skin contamination.

Because of the long time (decades) for any effects of plutonium inhalation to appear, there would be no deaths from acute doses.

Consequences to the Public. MACCS was used to determine the doses for the integrated populations. The source term was modeled as a 30-minute elevated release. The suspension term was modeled as three, 8-hour, ground level releases. For a discussion of the MACCS code and modeling results, please refer to section G.2.4.

The results of this analysis for a laboratory fire are summarized in Table G.5.6.15–13. No acute fatalities are predicted due to exposure to plutonium. If the fire remains within the laboratory, no excess LCFs are expected from this accident.

The results of this analysis for the wing fire are summarized in Table G.5.6.15–14. The consequences and risk are greater than with the laboratory fire because of the greater inventory of material when the entire wing is considered. If the total wing material is held to 13 pounds (6.0 kilograms), the doses increase slightly when the hydride-dehydride process is introduced because of the pyrophoric nature of the plutonium hydride.

The MEI doses for the Expanded Operations case are given in Table G.5.6.15–15. The MEI doses for the No Action Alternative would be less because the amount of material involved is less.

TABLE G.5.6.15–13.—*Summary Results for CMR Laboratory Fire, RAD–15*

Note: Approximated as 50 m.

Deposition Profile. The ground contamination levels for the Expanded Operations Alternative are given in Table G.5.6.15–16. The levels for the No Action Alternative would decrease correspondingly to the amount of material released for the No Action Alternative.

After publication of the Draft LANL SWEIS, DOE approved the CMR Basis for Interim Operations (BIO) (LANL 1998b) on August 31, 1998. That document includes a detailed analysis of a similar wing-wide fire. The CMR BIO takes a different approach to the accident, due to its stated need to identify the facility systems, processes, and controls necessary to prevent or mitigate the postulated accidents. The CMR BIO analysis results in a similar frequency, and MEI doses ranging from 10.8 rem to 42.8 rem, depending on the release mechanisms. The CMR BIO also assumes 95 percent meteorological conditions; whereas, the SWEIS uniformly assumed mean conditions. Given the differing assumptions in the scenarios, the large underlying uncertainties in such analyses, and the difference in meteorological modeling, these results demonstrate good agreement. Therefore, both analyses provide similar results to allow for the appropriate decision making.

G.5.6.16 *RAD–16, Plutonium Release Due to Aircraft Crash and Fire at CMR*

General Scenario Description

Accident Scenario RAD–16 involves the crash of an aircraft, accompanied by a fire, at the CMR Building, TA–3–29.

From the analysis of the aircraft operating in the vicinity of the CMR Building (section G.4.1.3), single- and multiple-engine general aviation aircraft and small military aircraft are capable of penetrating into a wing at the CMR Building. A fire then starts due to ignition of the planes fuel load and damage to a portion of the plutonium inventory in a wing. Because a range of outcomes is possible, the damage to the inventory is assumed to be proportional to the size of the burn area created by the fuel spill.

No Action Alternative Frequency Analysis

The analysis for the frequency of aircraft hitting the CMR Building and causing a release of hazardous material is presented in section G.4.1.3. The frequency for an aircraft penetration and resulting fire for the CMR Building is 3.5 x 10^{-6}. The aircraft that operate in the vicinity of LANL are predominantly general aviation, either single- or multiple-engine aircraft, with additional small military aircraft that make overflights in the area. These aircraft make up approximately 96 percent of the aircraft that have a greater than 10^{-6} chance per year of hitting and releasing material from the CMR Building.

It should be noted that the area of the CMR Building was reduced from the total building square footage to the combined areas of Wings 3, 5, 7, and 9. Because most of the hazardous materials are located in these areas, the reduction in area was deemed reasonable to account for the frequency of actually involving hazardous material in an aircraft crash induced fire. If the entire building is used for the calculations, the results change modestly (by about a factor of 2).

Expanded Operations, Reduced Operations, and Greener Alternatives Frequency Analysis

The frequency of an aircraft crash does not vary across the alternatives. Because no major changes in the location of hazardous material or their amounts are planned across alternatives, the probability of releasing these materials from an aircraft crash does not change.

TABLE G.5.6.15–16.—*Ground Contamination Levels (Expanded Operations Alternative)*

RADIAL DISTANCE	PLUTONIUM-239 GROUND CONCENTRATION (BQ/m^2)	
	LABORATORY FIRE	WING FIRE
0.0 to 1.0 km	2.0×10^{3}	4.0×10^{4}
1.0 to 2.0 km	3.8×10^{2}	7.5×10^{3}
2.0 to 3.0 km	1.9×10^{2}	3.7×10^{3}
3.0 to 4.0 km	1.2×10^{2}	2.2×10^{3}
4.0 to 8.0 km	4.7×10^{1}	9.2×10^{2}
8.0 to 12.0 km	1.9×10^{1}	3.7×10^{2}
12.0 to 20.0 km	7.5	1.5×10^{2}
20.0 to 30.0 km	3.0	5.8×10^{1}
30.0 to 40.0 km	1.7	3.3×10^{1}
40.0 to 60.0 km	8.2×10^{-1}	1.6×10^{1}
60.0 to 80.0 km	4.3×10^{-1}	8.5×10^{0}

BQ/m^2 = Becquerel per square meter

Uncertainties and Sensitivities Affecting the Frequency of RAD–16

There is a large number of data required in order to perform the DOE Standard 3014-96 calculations. In addition, the standard itself requires the use of numerous equations that are recognized to be approximations.

No Action Alternative Source and Suspension Term Calculations

Source Term. The source term is derived from consideration of the amount of material that can be involved in a fire and the subsequent amount that, through the dynamics of the accident and a fire, can be made available for atmospheric transport. Because there are several types of aircraft that contribute to the frequency term for an aircraft crash event, the source terms for the three most likely aircraft to impact the CMR Building, are listed in Table G.5.6.16–1.

Determination of the source term follows the standard format, as illustrated in Table G.5.6.16–1. The source term summary presented in this table is explained in subsequent sections.

The source terms are calculated by multiplying together each of the factors in the standard equation. These results represent the magnitude of the releases possible from different categories of aircraft that operate in the vicinity of LANL.

Material-at-Risk. Each wing in the CMR Building is limited to a maximum of 6.0 kilograms of equivalent plutonium-239 (LANL 1997a). The aircraft are assumed to penetrate only one wing. This scenario is based on the ability of aircraft to penetrate structures. This is assessed by determining whether or not dense components (such as an engine shaft, etc.) can penetrate the building. The fuel is conservatively assumed to enter the building through these penetrations. Thus, this scenario is not likely to involve more material than is in one wing of the CMR Building. MAR, regardless of the aircraft category, is considered to be the maximum inventory in a wing.

Material-at-Risk

Aircraft Category:

- *Single-Engine*
  - — *MAR = 6.0 kg Pu-239 (equivalent)*
- *Multiple-Engine*
  - — *MAR = 6.0 kg Pu-239 (equivalent)*
- *Small Military*
  - — *MAR = 6.0 kg Pu-239 (equivalent)*

Damage Ratio. DR will be determined by assessing how much of the inventory could be affected by the fire. To do this, a fire is assumed to start from a fuel spill that spreads across a portion of the CMR Building, and subsequently involves the inventory of plutonium in this portion. The Rocky Flats Risk Assessment Guide (RFETS 1994) was used to determine the burn area for the amount of fuel spilled. In this case, the entire fuel load of the appropriate aircraft is assumed to burn. Because the inventories are being used in various

TABLE G.5.6.16–1.—*Source Term for Aircraft Crash*

AIRCRAFT CATEGORY	MAR[a]	DR	ARF	RF	LPF	SOURCE TERM[a]
Single-Engine	6.0 kg Pu-239	.021	0.006	0.01	1.0	0.008 g Pu-239
Multiple-Engine	6.0 kg Pu-239	.068	0.006	0.01	1.0	0.024 g Pu-239
Small Military	6.0 kg Pu-239	.298	0.006	0.01	1.0	0.11 g Pu-239

[a] Pu-239 refers to equivalent plutonium-239.

gloveboxes and laboratories throughout a wing, the inventory is also assumed to be evenly distributed throughout the CMR wing. Thus, the damage ratio for a given aircraft category was determined to be the ratio of the burn area to the total square footage of one wing in the CMR Building.

Damage Ratio

Aircraft Category:

- *Single-Engine*
  - — *DR = 0.021*
- *Multiple-Engine*
  - — *DR = 0.068*
- *Small Military*
  - — *DR = 0.298*

The characteristics of these aircraft categories, as identified in the supporting documentation for DOE Standard 3014-96, were reviewed and the bounding fuel load was selected. The aircraft selected for these categories are: (1) the Piper Turbo line, with a fuel load of 128 gallons (486 liters) for the single-engine piston aircraft; (2) the Cessna Titan line, with a fuel load of 413 gallons (1,564 liters) for the multiple-engine piston aircraft; and (3) the F-16C, with a fuel load of 1,801 gallons (6,819 liters) for the small military aircraft (LLNL 1996). (The F-16C is typical of local military operations out of Kirtland Air Force Base in Albuquerque, New Mexico.)

According to the Rocky Flats Risk Assessment Guide (RFETS 1994), the estimate for burn area is a 250-square-foot (23-square-meter) burn area per 50 gallons (189 liters) of fuel.

The area of a wing, A_{WING}, at the CMR Building is approximately 30,250 square feet (275 feet by 110 feet). The burn areas identified below represent the following percentages of the total square footage for a wing at the CMR Building and therefore represent an equivalent DR for the plutonium inventory in a wing.

Burn Areas

Aircraft Category:

- *Single-Engine*
  - — F_{LOAD} = 128 gal.
  - — A_{BURN} = 640 ft^2
- *Multiple-Engine*
  - — F_{LOAD} = 413 gal.
  - — A_{BURN} = 2,065 ft^2
- *Small Military*
  - — F_{LOAD} = 2,802 gal.
  - — A_{BURN} = 9,005 ft^2

A_{BURN} = Burn area in square feet
F_{LOAD} = Aircraft fuel load in gallons

Burn Area Square Footage

Aircraft Category:

- *Single-Engine*
  - — *% Total Footage* (A_{BURN}/A_{WING} = *2.1%)*
  - — *DR = 0.021*
- *Multiple-Engine*
  - — *% Total Footage* (A_{BURN}/A_{WING} = *6.8%)*
  - — *DR = 0.068*
- *Small Military*
  - — *% Total Footage* (A_{BURN}/A_{WING} = *29.8%)*
  - — *DR = 0.298*

Airborne Release Fraction and Respirable Fraction. The DOE Handbook on airborne release fractions and respirable fractions, DOE Handbook 3010-94, presents values for ARF and RF based on the type of material, its form, and the nature of the event (e.g., fire, explosions, etc.). The ARF and RF values are selected for plutonium in powder form. These values represent the highest numbers for ARF and RF of the material in the CMR Building even though not all of the material in the CMR Building is in the form of a powder. For a fire, the recommended ARF and RF values are 0.006 and 0.01 (DOE 1994d).

Airborne Release Fraction and Respirable Fraction

Aircraft Category:

- *Single-Engine*
  - *ARF = 0.006*
  - *RF = 0.01*
- *Multiple-Engine*
  - *ARF = 0.006*
  - *RF = 0.01*
- *Small Military*
  - *ARF = 0.006*
  - *RF = 0.01*

Leak Path Factor. Due to the nature of an aircraft crash into a building and subsequent fire, no credit is taken for confinement of the material by either the structure or potential accident debris. The material that is in a respirable form can then be transported through the atmosphere. LPF is therefore assumed to be 1.0.

Leak Path Factor

Aircraft Category:

- *Single-Engine*
  - *LPF = 1.0*
- *Multiple-Engine*
  - *LPF = 1.0*
- *Small Military*
  - *LPF = 1.0*

Suspension Term. The suspension term is derived from consideration of the amount of material that can be further dispersed from the site of the accident by the wind or other disturbances. The amount of material available for suspension is highly dependent on accident response and clean-up activities. However, due to the nature of an aircraft accident, it is assumed that the material at the site can be released into the atmosphere for the next 24 hours.

Determination of the suspension term follows the standard format, as illustrated in Table G.5.6.16–2. The summary of the suspension term, as presented in this table, is explained in subsequent sections.

The suspension terms are calculated by multiplying each of the factors in the standard equation together. These results represent the magnitude of the suspension releases possible from different categories of airplanes that operate in the vicinity of LANL.

Material-at-Risk. Because so little of the material is released due to the fire, most of the material remains at the site. Therefore, 6.0 kilograms equivalent plutonium-239 is considered the MAR for suspension from the release point.

Material-at-Risk

Aircraft Category:

- *Single-Engine*
  - *MAR = 6.0 kg Pu-239 (equivalent)*
- *Multiple-Engine*
  - *MAR = 6.0 kg Pu-239 (equivalent)*
- *Small Military*
  - *MAR = 6.0 kg Pu-239 (equivalent)*

TABLE G.5.6.16–2.—*Suspension Term Calculations (No Action Alternative)*

AIRCRAFT CATEGORY	MAR[a]	DR	ARR	RELEASE PERIOD	RF	LPF	SUSPENSION TERM[a]
Single-Engine	6.0 kg Pu-239	0.021	4×10^{-6}/hr	24 hrs	1.0	1.0	0.008 g Pu-239
Multiple-Engine	6.0 kg Pu-239	0.068	4×10^{-6}/hr	24 hrs	1.0	1.0	0.024 g Pu-239
Small Military	6.0 kg Pu-239	0.298	4×10^{-6}/hr	24 hrs	1.0	1.0	0.11 g Pu-239

[a] Pu-239 refers to equivalent plutonium-239.

Damage Ratio. The DR is the same as the source term release. Material that was not damaged by the initial event is not considered available for suspension releases.

> ***Damage Ratio***
>
> *Aircraft Category:*
> - *Single-Engine*
>   - *DR = 0.021*
> - *Multiple-Engine*
>   - *DR = 0.068*
> - *Small Military*
>   - *DR = 0.298*

Airborne Release Rate, Release Period, and Respirable Fractions. For the fire release, the appropriate ARR and RF values are 4.0 x 10^{-6} per hour and 1.0, respectively, because it is assumed that the source powder would be buried under some structural debris (DOE 1994d). The suspension is assumed to occur for 24 hours after the initial accident.

> ***Airborne Release Rate, Release Period, and Respirable Fraction***
>
> *Aircraft Category:*
> - *Single-Engine*
>   - *ARR = 4 x 10^{-6} per hour*
>   - *Release Period = 24 hours*
>   - *RF = 1.0*
> - *Multiple-Engine*
>   - *ARR = 4 x 10^{-6} per hour*
>   - *Release Period = 24 hours*
>   - *RF = 1.0*
> - *Small Military*
>   - *ARR = 4 x 10^{-6} per hour*
>   - *Release Period = 24 hours*
>   - *RF = 1.0*

Leak Path Factor. Because the material is exposed to ambient conditions, LPF was considered to be 1.0. ARR accounts for any protection of the material by the debris at the site.

> ***Leak Path Factor***
>
> *Aircraft Category:*
> - *Single-Engine*
>   - *LPF = 1.0*
> - *Multiple-Engine*
>   - *LPF = 1.0*
> - *Small Military*
>   - *LPF = 1.0*

Uncertainties and Sensitivities Affecting the Source Term for RAD–16

The suspension source term calculation extends for 24 hours. This is very conservative in that it is likely that fire fighting and HAZMAT response to the crash scene would be accompanied by extensive use of water and foam-based suppression systems. This application of suppressants would likely continue for some time to preclude flareup of the fire once it is extinguished, as well as precisely to limit further spread of plutonium contamination.

Expanded Operations, Reduced Operations, and Greener Alternatives Source and Suspension Term Analysis

The source and suspension terms do not vary across the alternatives. Because no major changes in the location of hazardous material or their amounts are planned across alternatives, the source and suspension terms do not change. The amount of material that could be involved in the accident varies and has been conservatively estimated based on the wing limits for the facility. These wing limits do not change across alternatives.

Consequences for Facility Workers

An aircraft crash is capable of killing or injuring a large fraction of the worker population in the impacted wing due to generation of missiles, structural damage, fire, etc. Workers in the CMR Building who are not directly affected by the crash and explosion or fire may be exposed to radiation as a result of plutonium inhalation.

Consequences for the Public

To determine the consequences, or dose, to the public, an average value was used, based on frequency weighting the source and suspension terms for each aircraft category. The total source term used for dose and excess LCF calculations is 0.69 equivalent plutonium-239 (Table G.5.6.16–3). The total suspension term is 0.21 PE-Ci (Table G.5.6.16–4).

MACCS was used to determine the doses for the integrated populations. The source term was modeled as a 30-minute elevated release. The suspension term was modeled as three, 8-hour, ground level releases. For a discussion of the MACCS code and modeling results, please refer to section G.2.4.

The results for this accident are summarized in Table G.5.6.16–5. The accident may result in fatalities to occupant(s) of the aircraft and to people on the ground. However, no acute fatalities from the release of plutonium are predicted to result from the postulated accident. The mean collective population dose is projected to total 56 person-rem (TEDE), resulting in 0.03 excess LCFs. Mean projected doses for MEIs (and their associated locations) and ground contamination levels are presented in Tables G.5.6.16–6 and G.5.6.16–7, respectively.

G.5.7 Facility Hazard Accidents

G.5.7.1 *WORK–01, Inadvertent High Explosives Detonation*

General Description of High Explosives Operations

High explosives (HE) processing facilities are located at LANL TA–8, TA–9, TA–11, TA–16, TA–28, and TA–37. HE processing activities include storage, synthesis, formulation, pressing, machining, assembly, quality assurance processes, shipping and receiving of HE and HE devices, and disposal. Los Alamos HE facilities were designed in accordance with U.S. Department of Defense (DoD) Ammunition and Explosives Safety Standards, DoD 6055.9 (now referenced in the DOE Explosives Safety Manual [DOE 1994g]). Processing equipment has been continually upgraded and modernized.

HE processing facilities are generally separated from other operations and are all within restricted areas that require DOE badges for access through security check stations. Access to all buildings is further controlled by locks on building entrances that require specially controlled keys. Additionally, all HE areas are patrolled by protective force guards.

Operational controls and the associated level of protection are based on the explosive hazard class. There are four hazard classes. Hazard Class I processes involve activities that are considered to have a high accident potential and are designed to be conducted remotely so that an accidental detonation vents the high pressure and fragments via a frangible wall away from inhabited areas. Examples of Class I activities include screening, blending, pressing, dry machining, and new explosives development. Hazard Class II activities involve a moderate accident potential; examples include weighing, some wet machining, assembly and disassembly, and environmental testing. Hazard Class III activities are designated as having a low accident potential and include storage activities and operations incidental to storage. Hazard Class IV consists of activities involving insensitive HE. This explosive type is so insensitive that a negligible probability exists for accidental initiation or transition from burning to detonation. Selected activities using insensitive HE, such as machining and pressing, are conservatively designated as Class I. Explosives and personnel limits and controls are used to minimize the quantity of explosives and

BQ/m^2 = Becquerel per square meter

the number of personnel to carry out an operation in a safe and efficient manner. Personnel may not work alone performing explosives activities that have a high risk of serious injury. Additionally, quantity-separation distance criteria are used to minimize collateral damage in the event of an accident.

General Scenario Description

Accident scenario WORK–01 involves the inadvertent detonation of HE material. Potential accidents involving hazardous or radioactive material are not considered, as their impacts are bounded by the chemical and radiological specific accidents, which have been already analyzed. Based on the foregoing operations/controls discussion, it is very unlikely that an accident would impact workers other than those directly involved in the explosives activity, and it would be extremely unlikely that any credible postulated event would involve the public. The number of individuals that may be injured or fatally harmed for a postulated event will vary depending on the quantity of explosives involved and the number of workers present. As discussed above, operational controls limit both parameters. Laboratory testing of small samples may involve only one worker, while assembly operations (e.g., TA–16–411) may vary from three to ten workers. Blast effects to individuals are summarized in Table G.5.7.1–1 and are taken from the tri-service manual on *Structures to Resist the Effects of Accidental Explosions* (U.S. Army et al. 1990). Generally, human tolerance to the blast output of an explosion is relatively high, with specific impacts dependent on the orientation of the individual to the blast front and the shape of the pressure front (fast or slow rise, stepped loading). The lungs are considered the critical target organ in blast pressure injuries. Considering the high level of human tolerance to blasts and fragment operational/design controls, it is more likely that a postulated explosive accident will result in worker injuries rather than fatalities.

No Action Alternative Frequency Analysis

Walkdowns of selected HE processing facilities and discussions with knowledgeable facility personnel did not identify the occurrence of any explosive blast accidents at LANL resulting in injuries or fatalities. Additionally, a search of 5 years of LANL occurrence report data (1990 through 1994 Type F Reports) did not identify any explosive blast accidents. Site-specific experience at Pantex results in an explosive accident frequency of 10^{-2} per year (DOE 1996a). Based on this DOE system experience and scaling for the level of worker activities (2,000 weapons operations annually at Pantex), an accident frequency range of 10^{-3} to 10^{-2} is estimated for the LANL No Action Alternative.

Expanded Operations Alternative Frequency Analysis

The level of HE operations activity compared to the No Action Alternative is projected to increase: (1) by 40 to 100 percent for fabrication activities, depending on the specific program supported; (2) by 50 percent for HE

TABLE G.5.7.1–1.—*Blast Effects to Humans Due to Fast-Rising Air Blasts (3 to 5 Minutes Duration)*

CRITICAL ORGAN OR EVENT	MAXIMUM EFFECTIVE PRESSURE (PSI)
Eardrum Rupture:	
Threshold	5
50 percent	15
Lung Damage:	
Threshold	30 to 40
50 percent	80 and above
Lethality:	
Threshold	100 to 120
50 percent	130 to 180
Near 100 percent	200 to 250

Note: Maximum effective pressure is the highest of incident pressure, incident pressure plus dynamic pressure, or reflected pressure.

waste treatment, QA efforts, and receiving, transportation, and storage; (3) by 40 percent for facility support functions; (4) by 25 percent for safety and mechanical testing; and (5) by undefined increases in the remaining capability areas (LANL 1996b). As a first order estimate, it is assumed that the overall increase in the level of HE operations corresponds to the projected increase in HE receiving, transportation, and storage activities. This is based on the observation that receiving, transportation, and storage operations would be expected to reflect the site-wide level of activities in support of HE operations. Consequently, HE handling and processing activities are projected to increase by 50 percent over the No Action Alternative level of effort. This level of change in operations is within the range of past operational activity levels. Consequently, it is concluded that past operational experience and the projected accident frequency for the No Action Alternative would be applicable.

Reduced Operations Alternative Frequency Analysis

The level of HE operations activity is projected to be decreased: (1) to 80 percent of the No Action Alternative level of effort for the safety/mechanical testing and quality assurance efforts; (2) to 75 percent of the No Action Alternative level of effort for test device assembly, stockpile surveillance, and above ground testing; (3) to 60 percent of the No Action Alternative level of effort for HE synthesis and production, HE and plastics development and characterization, HE receiving, transportation and storage, and facility support; (4) to 40 percent of the No Action Alternative level of effort for HE waste treatment; and (5) to a much reduced level of effort for fabrication in support of refurbishment and weapons research and development (LANL 1996b). As a first order estimate, it is assumed that the overall decrease in the level of HE operations corresponds to the projected decrease in HE receiving, transportation, and storage activities. This is based on the observation that receiving, transportation, and storage operations would be expected to reflect the site-wide level of activities in support of HE operations. Consequently, HE handling and processing activities are projected to decrease to 60 percent of the No Action Alternative level of effort. This level of variation is within the range of past operational activity levels. Consequently, it is concluded that past operational experience would be applicable and that the projected accident frequency would be at the low end of the range for the No Action Alternative.

Greener Alternative Frequency Analysis

The level of HE operations activity for each of the capability categories is projected to be comparable to the Reduced Operations Alternative (LANL 1996b). Consequently, as with the Reduced Operations Alternative, HE handling and processing activities are projected to decrease to 60 percent of the No Action Alternative level of effort, with a projected accident frequency at the low end of the range for the No Action Alternative.

Source Term Calculations

The postulated accident does not release hazardous or radiological material to the environment. Potential HE incidents involving either hazardous or radiological materials are bounded by accident scenarios CHEM–01 through CHEM–06 and RAD–01 through RAD–16.

Uncertainties and Sensitivities Affecting the Source Term for WORK–01

The potential for blast impacts beyond laboratory and operations personnel are extremely low, based on both LANL and DOE system-wide experience and controls.

Consequences of WORK–01 for Facility Workers and the Public

This accident is limited to facility workers. Access controls and operational boundaries preclude any significant impacts to members of the public. Table G.5.7.1–2 summarizes the analysis results for WORK–01.

G.5.7.2 *WORK–02, Biohazard Contamination of a Single Worker*

General Scenario Description

There are three scenarios in which a LANL worker could be exposed to a biohazard: (1) accidental exposure to a passive or active bacterium, fungus, virus, etc, being used in the HRL (TA–43) for research purposes; (2) contact with fecal material or other infected avian or mammalian bodily fluids during field research or monitoring and surveillance activities; or (3) exposure of health workers to infectious agents carried by workers visiting the clinic. Of these three potential exposures, the one with the highest probability is the accidental exposure during research and development activities involving biohazards in HRL.

The accident scenario WORK–02 involves the inadvertent biohazard contamination of a single worker during activities at TA–43–1 (HRL). Biohazards are present or will be present at TA–43 in passive or active states in some research and development activities. Biohazards may include facultative pathogens or obligate pathogens such as Clostridium, Pseudomonas, E. coli, saccharomyces, Bacillus, and (in the Expanded Operations Alternative) Hepatitis B.

Activities involving biohazards are conducted, monitored, and regulated by the LANL Institutional Biosafety Committee using guidelines from the National Institutes of Health (NIH) and the Centers for Disease Control and Prevention (CDC). This work is done according to Biohazard Level 2 controls; all waste materials from culture operations are treated to kill the infectious agents prior to disposal, using autoclave heating or viricides/bactericides. Biohazard Level 2 equipment and engineering controls include limited access to work areas, protective laboratory coats and gloves, and safety cabinets or isolation enclosures for any operations that have a high potential for creating aerosols containing microorganisms (LANL 1996b).

Due to the proximity of HRL to the Los Alamos County Medical Center, stringent administrative controls are used to control organisms and potentially contaminated biohazardous waste and research materials. Specific bacteria, such as spore formers, which can live in encysted state for periods of time without nourishment or water or air, can only be used after LANL senior management review, and special protocols are required. Work with live viral agents is prohibited except for engineered viral agents used as vectors for transferring genetic material which present

TABLE G.5.7.1–2.—*Summary Results for Scenario WORK–01*

ALTERNATIVE	ACCIDENT FREQUENCY	SOURCE TERM
No Action	0.001 to 0.01	Accidental injury or fatality from 1 to 15 operations personnel
Expanded Operations	0.001 to 0.01	Accidental injury or fatality from 1 to 15 operations personnel
Reduced Operations	0.001 to 0.01	Accidental injury or fatality from 1 to 15 operations personnel
Greener	0.001 to 0.01	Accidental injury or fatality from 1 to 15 operations personnel

negligible risk of infection. Research on HIV and other human pathogens is limited to genome mapping and other operations that do not involve the original or active biological material (LANL 1996b).

No Action Alternative Frequency Analysis

In contrast to the documented occurrence of laboratory-acquired infections in laboratory personnel, laboratories working with infectious agents have not been shown to represent a threat to the community (CDC 1993). The primary risks from microbiology laboratories are to laboratory workers, and are specific to the agent, for example (CDC 1993):

- *Hepatitis B*—accidental inoculation, exposure of broken skin or the mucous membranes of the eyes, nose, or mouth
- *Clostridium botulinum*—accidental inoculation; toxin may be absorbed after ingestion or following contact with the skin, eyes, or mucous membranes
- *Pseudomonas*—aerosol and skin exposure

The frequency of accidental infections from biohazards is judged by DOE to be no greater than 0.01 to 0.1 per year given the level of research and development activities. The potential for nonworker exposure is at least hundreds of times less than worker exposure probability and is not credible within the scope of this analysis at a probability of 10^{-6} per year.

Expanded Operations, Reduced Operations, and Greener Alternatives Frequency Analysis

No significant differences in activity levels are identified that would result in a greater risk of accidental infection compared with the No Action Alternative.

Uncertainties and Sensitivities Affecting the Frequency of WORK–02

Hepatitis B is a new potential source of infection in the Expanded Operations Alternative. However, no cases of infection to laboratory workers from any agent were reported in the review of laboratory accidents and incidents in the 1990's or in during several discussions with LANL personnel at TA–43 and the institutional biosafety committee. Accordingly, given the period of time in which TA–43–1 has operated and during which field operations have been conducted, the frequency estimate of 0.01 to 0.1 per year is considered to bound the actual frequency. This frequency is very conservative based on National Cancer Institute (NCI) and NIH statistics of research and development accidental biohazard infection and resulting infection during the 1990's, which would estimate the frequency not to exceed 0.001 (NIH 1996).

Source Term Calculations

This accident does not release hazardous material to the environment. The potential for infection of persons other than laboratory personnel is very low. Because any such infections would have to be first observed in laboratory personnel, the risks are dominated by these original infections. Infection of one laboratory worker is the most likely outcome, multiple worker infections are less likely, and the spread of an infection beyond laboratory or field operations personnel is incredible (less than 10^{-6}).

Uncertainties and Sensitivities Affecting the Source Term for WORK–02

The potential for exposures beyond laboratory personnel are very low, based on both LANL and industry-wide experience.

Consequences of WORK–02 for Facility Workers and the Public

This accident affects only laboratory research and development workers. The potential for public impact is judged to be nil. Table G.5.7.2–1 summarizes the analysis results for WORK–02.

G.5.7.3 *WORK–03, Inadvertent Nuclear Criticality Event*

General Scenario Description

WORK–03 involves an inadvertent criticality event, the most significant impacts of which are on workers in the immediate vicinity of the event (due to neutron and gamma exposure). Critical assemblies and experiments are routinely performed at Pajarito Site (TA–18), and were considered in RAD–03. Outside of TA–18, a criticality event, although unlikely in the absolute sense, is most likely to occur at TA–55–4 (Plutonium Facility). At this facility, the consideration would mainly be due to operations with fissile material in liquid solutions. While fissile material is handled in the solid form, it is considered to be much less likely to be involved in a criticality event than a solution (LANL 1996k).

Criticality events are capable of producing potentially lethal amounts of neutron and gamma radiation in a localized area. Depending upon the physical form of the system, such as a solution, the event may be accompanied by the release of plutonium through the aerosolization of the solution and also may produce fission products that might be released to the environment.

Historical Criticality Events

There have been several inadvertent criticality events with solutions since the 1940's. Some of these events are summarized in Table G.5.7.3–1. As demonstrated by the table, these events occur infrequently, and each tends to be unique in nature, making a quantitative frequency estimation difficult. Most recently, there were two criticality events reported in Russia. The first was reported to be an excursion in a uranium solution in May 1997. Later, in June of the same year, a fatality was reported from a criticality event; however, this one apparently involved a solid fueled critical assembly. Details on these two accidents are not sufficient at this time to provide further discussion of them and their potential implications here.

LANL SAR Evaluations of Inadvertent Criticality Event

The TA–55 SAR identifies a nuclear criticality event in the uranium/plutonium separations process as a bounding event. The evaluation is essentially generic, applying to all deep-well,

TABLE G.5.7.2–1.—*Summary Results for Scenario WORK–02*

ALTERNATIVE	ACCIDENT FREQUENCY	SOURCE TERM
No Action	0.01 to 0.1	Accidental exposure of one laboratory worker resulting in diagnosed infection. No public impact.
Expanded Operations	0.01 to 0.1	Accidental exposure of one laboratory worker resulting in diagnosed infection. No public impact.
Reduced Operations	0.01 to 0.1	Accidental exposure of one laboratory worker resulting in diagnosed infection. No public impact.
Greener	0.01 to 0.1	Accidental exposure of one laboratory worker resulting in diagnosed infection. No public impact.

TABLE G.5.7.3–1.—*Summary of Inadvertent Solution Criticality Events (1945 to the Present)*

DATE	LOCATION	FISSIONABLE MATERIAL	PHYSICAL ARRANGEMENT	TOTAL FISSION YIELD	DESCRIPTION AND CONSEQUENCES
53/03/15	Mayak, Urals (Russia)	Plutonium solution (31 l)	Steel vessel	2.5×10^{17}	Human error (chief operator transferred solutions from two vessels into a single vessel); chief received 1,000 rad and another operator received 100 rad
54/05/26	Oak Ridge	Uranium solution (18.3 kg Uranium-235, 55.4 l of solution)	Cylindrical annulus, unreflected	1×10^{17}	Shift of poison; no physical damage
56/02/01	Oak Ridge	Uranium solution (27.7 kg Uranium-235, 58.9 l of solution)	Cylinder, unreflected	1.6×10^{17}	Geometry change; warping of bottom of cylinder
57/04/12	Mayak, Urals (Russia)	Uranium solution	Cylinder	2×10^{17}	Human error (leading to oxalate precipitation); lethal to operator, five others developed symptoms of radiation sickness
58/01/02	Mayak, Urals (Russia)	Uranium solution	Tank with control rod	2.3×10^{17}	Human error (staff decided to tip tank to speed up draining of solution, in violation of procedures), bodies acted as reflector; 3 deaths, fourth operator developed radiation sickness and lost sight
58/06/16	Oak Ridge	Uranium solution (2.5 kg Uranium-235, 56 l of solution)	Cylinder, concrete reflected below	1×10^{16}	Valve leaked or left open; no physical damage; $1,000 loss
58/12/30	Los Alamos	Plutonium solution (3.27 kg Plutonium, 168 l of solution)	Cylinder, water reflected below	1.5×10^{17}	Human error (failure to follow procedure); lethal to operator; no physical damage
59/10/16	Idaho Falls	Uranium solution (34.5 kg Uranium-235, 800 l of solution)	Cylinder, concrete reflected below	1×10^{17}	Sparge gage plugged; no physical damage; $62,000 loss

TABLE G.5.7.3–1.—*Summary of Inadvertent Solution Criticality Events (1945 to the Present)*-Continued

DATE	LOCATION	FISSIONABLE MATERIAL	PHYSICAL ARRANGEMENT	TOTAL FISSION YIELD	DESCRIPTION AND CONSEQUENCES
60/12/05	Mayak, Urals (Russia)	Plutonium solution	Cylinder, unfavorable geometry	1×10^{17}	Human error (failure to check results after mass discrepancy discovered; transfer of solution to unfavorable geometry); several people exposed to up to 5 rad
61/01/25	Idaho Falls	Uranium solution (8 kg Uranium-235, 40 l of solution)	Cylinder	6×10^{17}	Human error (instruction misinterpreted); no physical damage; $1,000 loss
61/08/14	Siberian Chemical Combine (Russia)	Uranium hexafluoride accumulated in oil	Cylinder	1×10^{16}	Human error (assumed first criticality alarm was false, restarted facility); operator received 200 rad
62/09/07	Mayak, Urals (Russia)	Plutonium solution, dissolution of Plutonium scrap in nitric acid; 1.2 kg Plutonium	Cylinder	2×10^{17}	Settling of solution after stirrer turned off; doses low due to no one near dissolver and lead shielding on dissolver
63/01/30	Siberian Chemical Combine (Russia)	Uranium solution	Cylinder	7.9×10^{17}	Human error (poor record keeping, mislabeling of uranium concentration); four persons received 6 to 17 rad at a distance of 10 meters
63/12/13	Siberian Chemical Combine (Russia)	Uranium solution	Cylinder, hemispherical bottom	2×10^{17}	Accumulation of uranium solution in trap; no injuries
64/07/24	Wood River Junction	Uranium solution (2.64 kg Uranium-235)	Cylinder, unreflected	1.1×10^{17}	Human error (failure to follow procedure); lethal to operator; no physical damage
65/12/16	Mayak, Urals (Russia)	Uranium solution	Cylinder	7×10^{17}	Human error (excess loading of uranium into solution, cessation of stirring); several staff exposed up to 30 mR
70/08/24	Windscale (U.K.)	Plutonium complex (2.5 kg Plutonium, 100 l of solution)	Cylinder	1×10^{15}	Plutonium accumulated in organic; no physical damage

Source: DOE 1994b unless otherwise noted.

wet chemistry operations. The accident assumes that as a result of multiple overbatching errors, the fissile material inventory for a glovebox substantially exceeds the allowable limit. A vessel overpressure or some other mechanism results in the rupture of adjacent vessels containing rich solution. The solution collects in a deep well, followed by a separate influx of water (failure of a water line), resulting in a single-pulse solution criticality event yielding 5 x 10^{17} fissions. The resulting fission products and plutonium aerosol are processed through the ventilation system and released from the south exhaust stack (LANL 1996k). Based on a PRA, the TA–55 SAR estimates the frequency of a solution criticality event at 6 x 10^{-7} per year per operation (LANL 1996k). Because there are hundreds of operations, the cumulative frequency of a criticality accident in TA–55–4 is estimated to be in the range from 10^{-6} to 10^{-4} per year (LANL 1996k).

The TA–55–4 SAR includes exposure analyses for the maximum off-site individual (MOI) at Royal Crest Trailer Park, 2,952 feet (900 meters) away, for an unmitigated scenario (no HEPA filtration, LPF = 1) and for a realistic scenario (with HEPA filtration). The unmitigated MOI dose is 1.6 rem; whereas, the realistic MOI dose is 35 millirem. Regarding consequences to workers, the SAR states that anyone within 16 feet (4.9 meters) of the criticality location would receive more than 500 rem. The dose at 33 feet (10 meters) drops to 80 rem. The number of people in the room varies with the work being done, but is most likely to be two or three people (LANL 1996k).

No Action Alternative Frequency Analysis

Consistent with the TA–55 SAR analyses, which account for LANL-specific design and operational practices, the frequency of an accidental critical excursion is estimated to be no greater than 10^{-6} per operation; but, considering that there are hundreds of operations per year, the frequency of accidental criticality is likely to be in the range of 10^{-6} to 10^{-4} per year.

Expanded Operations, Reduced Operations, and Greener Alternatives Frequency Analysis

Although there is an increase in activities involving fissile materials in the Expanded Operations Alternative (as a result of pit production), most of these activities involve solid systems that do not contribute significantly to criticality accident frequency. Other alternatives do not vary significantly in the level of activities that are most likely to give rise to inadvertent criticality events. Accordingly, no difference in frequency is identified across the alternatives.

Uncertainties and Sensitivities Affecting the Frequency of WORK–03

Historical experience has demonstrated that criticality accidents are unpredictable, unique events that do not lend themselves to a straightforward frequency determination. Accordingly, this analysis only attempts to establish a range, rather than an individual value, for the frequency.

Source Term Calculations

Given the low MOI exposure estimates in the TA–55–4 SAR (doses to the MOI of less than 50 millirem), no public exposure estimates will be performed for this accident because it would screen as insignificant based on the SWEIS accident analysis screening methods (off-site exposure of less than 500 millirem).

Consequences of WORK–03 for Facility Workers and the Public

The consequences to the public from WORK–03 are insignificant. Workers located close to the site of the criticality event (i.e., within 30 feet [9.2 meters]) can receive doses of neutron and gamma radiation on the order of

500 rem or higher. Acute radiation injuries and deaths are possible within this radius. Workers located elsewhere in the facility could be exposed to volatile fission products (noble gases, radioiodines, etc.) that evolve from the solution criticality accidents. This is the same for all options. Table G.5.7.3–2 summarizes the analysis results for WORK–03.

G.5.7.4 *WORK–04, Inadvertent Worker Exposure to Electromagnetic Radiation*

General Scenario Description

Accident scenario WORK–04 involves the inadvertent exposure of one or more workers to electromagnetic radiation. Used in this context, electromagnetic radiation refers to exposure to x-rays, accelerator beams, lasers, or radio frequency (RF) sources. Such radiation sources are used widely in various facilities at LANL, especially lasers.

No Action Alternative Frequency Analysis

The WORK–04 accident scenario is meant to represent a class of accidents involving inadvertent exposure of workers to the types of sources described above. Accordingly, there is no unique sequence of events that can be analyzed for frequency and conditional probability. However, these accidents typically involve a failure of an interlock device and/or the failure of the workers to follow procedures and/or observe precautions that could have prevented the exposure.

Events involving electromagnetic radiation sources that occur more often than once in 10 years (and that have a frequency above 0.1 per year) are accounted for and discussed under the subject of nonionizing radiation elsewhere in the SWEIS. Due to the large number of sources of electromagnetic radiation in use at a broad range of facilities at LANL, it is concluded that, in sum, the frequency of accidents resulting in worker injury or fatality is unlikely to be less than 1 in 100 per year (i.e., a frequency of less than 0.01 per year). This places bounds of 0.01 to 0.1 per year for the WORK–04 accident.

Expanded Operations, Reduced Operations, and Greener Alternatives Frequency Analysis

No significant differences in activity levels are identified that would result in a greater risk of accidental exposure of workers to electromagnetic radiation compared with the No Action Alternative. Thus, no difference in frequency is identified across the alternatives.

Uncertainties and Sensitivities Affecting the Frequency of WORK–04

Uncertainties are not considered to substantially influence the estimated frequency range for this accident due to the large number of potential sources to which workers could be exposed.

TABLE G.5.7.3–2.—*Summary Results for Scenario WORK–03*

ALTERNATIVE	ACCIDENT FREQUENCY	SOURCE TERM AND CONSEQUENCES
No Action	10^{-6} to 10^{-4}/year	Fatalities to nearby workers. No consequences to the public.
Expanded Operations	10^{-6} to 10^{-4}/year	Fatalities to nearby workers. No consequences to the public.
Reduced Operations	10^{-6} to 10^{-4}/year	Fatalities to nearby workers. No consequences to the public.
Greener	10^{-6} to 10^{-4}/year	Fatalities to nearby workers. No consequences to the public.

Administrative controls enforced by LANL management are similar across LANL and should not be associated with significant variation in risk from facility to facility.

Source Term Calculations

This accident does not release hazardous material to the environment; hence, no source term calculations are required.

Uncertainties and Sensitivities Affecting the Source Term for WORK–04

This issue is not applicable to WORK–04 because no source terms are calculated.

Consequences of WORK–04 for Facility Workers and the Public

Due to the nature of facility designs and the nature of the hazards involved, no public impact is expected. Worker consequences could range from minor injuries to major eye injuries, and could include fatalities under some circumstances. The number of workers injured or killed by any given accident would be expected to be small (typically one) because it is unlikely that a group of workers would all violate administrative controls and have this violation result in injury or fatality. This is not to say that this never happens, because it does; but by far and away the most likely outcome is a single worker being affected by any one event. Table G.5.7.4–1 summarizes the analysis results for WORK–04.

G.5.7.5 *Work–05, Plutonium Release from Degraded Vault Storage Container at TA–55–4*

General Scenario Description

TA–55, the Plutonium Facility at LANL, handles containers of plutonium as part of day-to-day operations. Among the current activities at TA–55 is the repackaging of material stored in vault rooms in the facility's basement. The plutonium in these containers is being repackaged due to the degraded nature of some of the containers. The repackaging activity is part of a program to implement the DNFSB Recommendation 90-4.

In order to repackage the plutonium, the containers must be retrieved, the plutonium taken out, and the material repackaged. While handling the container, there is the possibility of the container being dropped and some portion of the contents being spilled. If this accident occurs while the building HEPA filters and HVAC systems are operating, very little of the plutonium can escape the facility. Thus, this accident presents the frequency for dropping a degraded container and qualitatively evaluates the exposure of facility workers to this plutonium spill.

The impacts to the public from this type of accident was presented in section G.5.6.10. This discussion presents the frequency for the drop of the container and the exposure of

TABLE G.5.7.4–1.—*Summary Results for Scenario WORK–04*

ALTERNATIVE	ACCIDENT FREQUENCY	CONSEQUENCES
No Action	0.01 to 0.1/year	Typically one worker injury or fatality; small likelihood of two or more workers being simultaneously affected.
Expanded Operations	0.01 to 0.1/year	Same as No Action Alternative.
Reduced Operations	0.01 to 0.1/year	Same as No Action Alternative.
Greener	0.01 to 0.1/year	Same as No Action Alternative.

workers within the facility only. The public impacts were discussed previously.

For the contents of a container to be spilled, the containers must be corroded or have some other physical damage. LANL has currently retrieved about 1,450 containers and found, through visual inspection, 361 containers to have some defect. Of these 361 containers, 82 have lost outer containment, or approximately 5.5 percent have outer containment failure. The rate of inner containment failure is estimated to be 2 percent. To have a release of material, a container would have to have both its outer and inner container fail during a drop. The contents would then have to be spilled. For this accident, the frequency is therefore dependent on dropping a container that has sufficient damage, such as loss of containment, in order to spill the material.

Once the containers are repackaged, risk will be reduced because of upgrades to the containers and the required stability of the material inside.

For further information, DOE Standard 3013-96 (DOE 1996e) addresses the requirements for containers for long-term (at least 50 years) storage of plutonium. To meet the standard, plutonium-bearing materials must be in stable forms and packaged in containers designed to maintain their integrity under both normal storage conditions and anticipated handling accidents for at least 50 years (DOE 1996e). The standard applies to metal, oxide, and alloys containing at least 50 percent plutonium by mass, and containing less than 3 percent plutonium-238 by mass (DOE 1996e). The quantity of metal per container should be as close as practical to, but not exceed, 9.68 pounds (4.40 kilograms). Stored metal pieces are required to have thicknesses greater than 0.04 inches (1.0 millimeters) and have specific surface areas less than 71 inches/2 pounds (1 centimeter/2 grams) to reduce potential pyrophoric tendencies (DOE 1996e). The quantity of oxide by container should be as close as practical to, but not exceed, 10.97 pounds (5.00 kilograms), representing the plutonium dioxide equivalent of 9.68 pounds (4.40 kilograms) of plutonium metal. The oxides are required to be thermally stabilized with less than 0.5 percent mass loss-on-ignition (DOE 1996e). The containers are required to include a minimum of two nested, sealed containers, and have at least one container that remains leak tight after a free drop from a 30-foot (9-meter) height into a flat, essentially unyielding, horizontal surface (DOE 1996e). The containers are required to have a cylindrical geometry not exceeding 4.9 inches (12.5 centimeters) outside diameter or 10 inches (25.4 centimeters) external height (DOE 1996e). Although the risk will be reduced once the plutonium is repackaged, new risk numbers are not calculated. These numbers are considered representative of the type of worker risk that exists when handling plutonium in LANL nuclear facilities.

No Action Alternative Frequency Analysis

Table G.5.7.5–1 summarizes the frequency analysis for a container drop in TA–55. Because there are two types of containers, the frequency for dropping each container is presented. The terms for the equation are explained in subsequent sections. Table G.5.7.5–2 presents the number of container handling operations.

For the purposes of this analysis, the containers are being tracked as two types of containers. Most containers are doubly contained drums, (i.e., drums that have an inner and outer container, and are hermetically sealed). The other type has various names such as food pack cans, or dressing jars. These names were derived from their general appearance to distinguish one container over another. However, these cans would sustain similar damage when dropped. The drums would have a different failure rate than the metal cans when dropped, so the containers are being tracked as two separate types.

TABLE G.5.7.5–1.—*Frequency Analysis for a Container Drop in TA–55*

SCENARIO	NUMBER OF CONTAINERS HANDLED PER YEAR	HEP FOR CONTAINER DROP	PROBABILITY OF DEGRADED INNER CONTAINER	PROBABILITY OF DEGRADED OUTER CONTAINER	FREQUENCY OF CONTAINER DROP AND SPILL (SPILL PER YEAR)
Drums	972	0.001	0.055	0.02	0.0011
Nonhermetically Sealed Containers	228	0.001	1.0	1.0	0.23

TABLE G.5.7.5–2.—*Number of Container Handling Operations*

CONTAINER TYPE	TOTAL NUMBER OF CONTAINERS	PERCENTAGE OF CONTAINERS REPACKAGED PER YEAR	NUMBER OF HANDLING OPERATIONS TO REPACKAGE	HANDLING OPERATIONS PER YEAR
Drums	5,830	17	1	972
Metal Cans	1,370	17	1	228

Because the repackaging effort will take approximately 6 years, the repackaging rate was estimated to be 17 percent of the total containers each year.

Each container will be handled once before being placed into a DOE Standard 3013-96 container. Although the entire repackaging process may have additional steps, this is the activity where the material is most likely to be spilled and have worker exposure. Thus, the number of degraded container handling operations is 972 drum operations and 228 metal can operations for a total of 1,200 handling operations of degraded containers per year.

Generally, dropping a container does not involve equipment failure, but rather, errors in setting up the equipment properly. This failure is similar to that of checking the status of equipment, if the status of the equipment affects one's safety when performing the task (Swain and Guttmann 1983). As shown in Table G.5.7.5–3, the probability of dropping a container, for either type, is therefore estimated to be 0.001.

In order for a container drop to result in a material spill and exposure to workers, a degraded container must be dropped. For drums, the probability of this occurring is assumed to be directly proportional to the number of drums that have both the inner and outer containers damaged. From existing inspections of containers, about 5.5 percent have outer containment failure, and about 2 percent have inner containment failures. Given that the inner containment failure is not linked to outer containment failure, the probability of both of these conditions existing

TABLE G.5.7.5–3.—*Human Error Probability (HEP), Container Drop*

SCENARIO	HEP, CONTAINER DROP
Drums	0.001
Metal Cans	0.001

is about 0.11 percent (as shown in Table G.5.7.5–4).

For the metal cans, the probability of these containers failing is assumed to be 1.0. These containers were used to pack plutonium metal (LANL 1996k). Although some of these containers had inner and outer containers, they lacked a hermetic seal. Without the hermetic seal, the metal could be oxidized. Also, the inner container was often placed in a plastic bag and then placed inside the outer container. Normally, degradation of the plastic bags was not a problem because the plutonium metal was not stored in them for long periods of time. However, because the plastic bags decompose into various organic compounds through alpha-particle-induced decomposition and can cause the metal and containers to corrode, the plutonium metal must be repackaged. For these reasons, the conservative assumption was made that if a container is dropped then the material is spilled, therefore, by definition, the container is a degraded container.

For workers, the rate of plutonium exposure from these types of accidents is about 1 in 5 years.

Expanded Operations, Reduced Operations, and Greener Alternatives Frequency Analyses

The same type of activities will be conducted for each of the alternatives. Because no appreciable changes in these activity levels are anticipated for the various alternatives, the results of the frequency analysis for the No Action Alternative remains the same for these alternatives.

Uncertainties and Sensitivities Affecting the Frequency of WORK–05

The assumption that the "metal can" containers will spill material if dropped is considered a conservative assumption for this analysis.

Source Term Calculations

If the entire contents of the package was spilled, the amount of material that could be inhaled is 2.7 grams of plutonium (see section G.5.6.10, Source Term). It is not likely that a worker would inhale this much plutonium. The worker has personnel protective equipment that would be used in response to the accident. Alarms would also sound if plutonium became airborne as part of the accident and limit the exposure of other workers in the area.

Expanded Operations, Reduced Operations, and Greener Alternatives Source Term Analyses

Because the MAR is associated with an individual container-handling operation and LANL will continue to perform these types of activities in order to carry out any assigned mission, the source term would not change.

Worker Consequences

Significant but nonlethal doses are possible to the workers handling the plutonium. Any adverse impacts would be mitigated by prompt use of protective equipment and/or prompt

TABLE G.5.7.5–4.—*Probability of Dropping a Degraded Container*

SCENARIO	PROBABILITY OF INNER CONTAINMENT FAILURE	PROBABILITY OF OUTER CONTAINMENT FAILURE	PROBABILITY OF HANDLING A DEGRADED CONTAINER
Drums	0.02	0.55	0.0011
Metal Cans	1.0	1.0	1.0

exiting of the immediate vicinity for those not involved in clean-up activities. Table G.5.7.5–5 summarizes the analysis results for WORK–05.

G.6 UNCERTAINTIES AND SENSITIVITIES

In principle, one could estimate the uncertainty associated with each step of the analysis for each accident scenario, and predict the uncertainty in the results (frequency, source term, consequences, risk, etc.). However, conducting such a full-scale quantitative uncertainty analysis is neither practical nor a standard practice for a study of this type. Instead, the analysis is intended to ensure, through judicious selection of release scenarios, models, and parameters that the results represent and bound the actual risks.

This is accomplished by making assumptions at each step of the calculations. The models, model parameters, and release scenarios are selected in such a way that most intermediate results and the final estimate of impacts are greater than what would be expected should the events actually occur. As a result, even though the range of uncertainty in a quantity might be large, the values selected for quantification are conservative, so the chance that the actual quantity will be greater than the calculated value is low.

The approach taken for quantification of accident risks is such that most of the uncertainty in the results lies on the downside of the values presented. That is, there is a small chance that the actual value lies above those presented, but a very large chance that the actual value lies below those presented in this appendix and in chapter 5 of volume I.

TABLE G.5.7.5–5.—*Summary Results for Scenario WORK–05*

ALTERNATIVE	ACCIDENT FREQUENCY	WORKER CONSEQUENCES
No Action	0.23	Plutonium exposure to one or two workers. Adverse exposure limited by use of personnel protective equipment.
Expanded Operations	No Change	No Change
Reduced Operations	No Change	No Change
Greener	No Change	No Change

APPENDIX H
SUPPLEMENTAL ANALYSIS FOR THE ENHANCEMENT OF PIT MANUFACTURING AT LOS ALAMOS NATIONAL LABORATORY, STOCKPILE STEWARDSHIP AND MANAGEMENT PROGRAMMATIC ENVIRONMENTAL IMPACT STATEMENT

Department of Energy
Washington, DC 20585

March 13, 1998

MEMORANDUM FOR GENE IVES
DEPUTY ASSISTANT SECRETARY FOR MILITARY APPLICATIONS AND STOCKPILE MANAGEMENT

ROBIN STAFFIN
DEPUTY ASSISTANT SECRETARY FOR RESEARCH AND DEVELOPMENT

FROM: Victor H. Reis
Assistant Secretary for Defense Programs

SUBJECT: Determination re: Supplement Analyses for the National Ignition Facility (NIF) and Pit Production at Los Alamos National Laboratory (LANL)

I have reviewed the attached Supplement Analyses on (1) the Use of Hazardous Materials in NIF Experiments at LLNL and (2) Enhancement of Pit Manufacturing at LANL in accordance with applicable Departmental regulations as well as your March 11, 1998, memorandum. I have approved the Supplement Analyses and have concluded that: (1) there are no substantial changes in the proposed actions that are relevant to environmental concerns; and (2) there are not significant new circumstances or information relevant to environmental concerns and bearing on the proposed actions or their impacts. Therefore, I have determined, that in accordance with 40 CFR 1502.9(c) and 10 CFR 1021.314(c), that neither a new Stockpile Stewardship and Management (SSM) Programmatic Environmental Impact Statement (PEIS) nor a supplement to the existing SSM PEIS is required.

**SUPPLEMENT ANALYSIS:
ENHANCEMENT OF PIT MANUFACTURING
AT LOS ALAMOS NATIONAL LABORATORY,
STOCKPILE STEWARDSHIP AND MANAGEMENT
PROGRAMMATIC ENVIRONMENTAL IMPACT STATEMENT**

March 1998

SUMMARY

Recently, several issues have been raised regarding whether or not the 1996 Department of Energy (DOE) Stockpile Stewardship and Management (SSM) Programmatic Environmental Impact Statement (PEIS) analysis of locating a enhanced pit manufacturing capability at Los Alamos National Laboratory (LANL) should be supplemented due to new or overlooked information. Broadly, these issues have to do with: whether or not connected facilities were considered in the SSM PEIS; whether or not the upgrades to deteriorating facilities at LANL should have been considered in the SSM PEIS; and whether or not more recent information should be considered.

DOE has analyzed these issues in this Supplement Analysis and has concluded that there is no need to prepare a supplemental SSM PEIS to address reestablishing pit fabrication capability. The issues raised were either covered in the SSM PEIS and so were available to the decisionmaker; were project-specific issues related to the implementation of SSM decisions at LANL and so would be subject to subsequent tiered environmental review and decisionmaking; or were preliminary information and so would be subject to future review at such time as they are ripe for decision. Through this Supplement Analysis DOE recommends that neither a Supplemental PEIS, a new EIS, nor an amended ROD be prepared.

INTRODUCTION

Purpose of this Document

This document is a Supplement Analysis prepared to assist the Department of Energy (DOE) to determine whether or not to prepare a Supplemental Programmatic Environmental Impact Statement (PEIS) for its Stockpile Stewardship and Management (SSM) Program. This Supplement Analysis specifically addresses the issue of those aspects of DOE's nuclear weapons pit manufacturing capability and capacity (a "pit" is a central component of a nuclear weapon) that were assigned to Los Alamos National Laboratory (LANL) in the SSM Record of Decision (ROD).

Background - SSM PEIS

Before addressing whether or not the SSM PEIS should be supplemented, consideration of some background information regarding the PEIS, its intent, the decisions reached, and the formulation of issues, is presented. This information assists in arriving at conclusions and recommendations regarding supplementing the SSM PEIS, preparing a new EIS to address pit manufacturing, or changing the SSM ROD. The SSM PEIS was prepared in accordance with the National Environmental Policy Act (NEPA) [42 USC 4321 et seq.], the Council on

Environmental Quality (CEQ) NEPA implementing regulations [40 CFR 1500], and the DOE NEPA implementing regulations [10 CFR 1021].

In March 1996 DOE published a Draft PEIS on its nuclear weapons SSM Program [A.R. No. I-1385]; DOE published the Final SSM PEIS in September 1996 [DOE/EIS-0236, A.R. No. I-1561]. The SSM PEIS analyzed how DOE might carry out its nuclear weapons mission assignments, at a programmatic level, including alternative locations where DOE might assign various SSM missions. A ROD, based in part on the environmental analyses in the SSM PEIS, was issued on December 19, 1996 [61 FR 68014, A.R. No. I-1606, A.R. No. VII.B-26]. The SSM PEIS and ROD were intended to address the programmatic decisions facing DOE regarding implementation of its SSM Program. A two-tiered NEPA strategy was adopted, wherein implementing the programmatic decisions at a site-specific level in many cases would be accomplished through subsequent tiered project-specific NEPA reviews [SSM PEIS Vol. I, Sec. 1.5, p. 1-8; see also SSM ROD, Sec. 3.A.4].

The SSM PEIS and the SSM ROD covered those proposed actions which were the salient decision factors for determining how DOE would implement the SSM program for the foreseeable future. One of the proposals involved "Reestablishing Manufacturing Capability and Capacity for Pit Components" [SSM PEIS, Vol. I, Sec. 2.5.3, p. 2-11]. Capability is the practical ability to perform a basic function, and SSM capabilities are needed independent of future nuclear weapons stockpile sizes. Capacity is the size of the capability; in other words, the number of components that could be fabricated at a specific facility or a specific time. The SSM PEIS analyzed the potential capacity at different sites to support a potential nuclear weapons stockpile of various sizes (numbers of weapons) in order to examine the sensitivity of programmatic decisions to transfer weapons manufacturing activities to sites such as LANL. [SSM PEIS Vol. I, Sec. 1.1, p. 1-2.]

DOE needed to reestablish the capability to produce stockpile-ready pits that was lost when in 1992 DOE ceased plutonium pit manufacturing operations at its Rocky Flats Plant (RFP) (now known as the Rocky Flats Environmental Technology Site) in Colorado [SSM PEIS Vol. I, Sec. 2.5.3, p. 2-11]. The programmatic question addressed in the SSM PEIS and ROD related to pit fabrication was which DOE site should receive this mission assignment. Programmatic alternatives for locating pit fabrication alternatives were limited to sites which had some level of technical or facility infrastructure [SSM PEIS Vol. I, Sec. 2.5.3, p. 2-11; SSM PEIS Vol. I, Sec. 3.4.3, p. 3-57]. SSM PEIS alternatives included reestablishing pit capability and capacity at the DOE's LANL; reestablishing the capability and capacity at the DOE's Savannah River Site (SRS); or to continue to rely on the existing capability and capacity at LANL and the DOE's Lawrence Livermore National Laboratory (LLNL). LANL's facility infrastructure is located in several buildings at different Technical Areas (TAs). The three siting alternatives discussed and analyzed in the SSM PEIS were:

1. No Action (continue to use existing limited capabilities at LANL and continue to use the limited capability at LLNL to support material and technology development);
2. Reestablish pit fabrication at LANL (use existing facilities at TA-55, -3, -8, -50 and -54, and construct some upgrades);
3. Reestablish pit fabrication at SRS (use space in existing "hardened" nuclear facilities with extensive equipment and construction upgrades).

The SSM PEIS provided a comparative analysis of the programmatic impacts that would be expected to occur if the pit fabrication capability were to be reestablished at either LANL or SRS, compared against the No Action baseline [SSM PEIS, Vol. I, Section 4.6.3, p. 4-276]. Because construction of new buildings was not anticipated to be needed in order to assign the pit fabrication mission to LANL, notable environmental impacts were primarily limited to those from operations, such as radiological impacts, and socioeconomics. If the pit fabrication mission had been relocated to SRS, some new construction would have been needed [SSM PEIS, Vol. I, Section 4.3.3, p. 4-107]. Appendix A [SSM PEIS, Vol. II, Sec. A.1.5, p. A-28] *provided greater detail of the Defense Programs* Facilities in use at LANL, including the Chemical and Metallurgical Research (CMR) Building and Sigma Complex at TA-3, and the plutonium (Pu) facilities at TA-55 [Table A.1.5-1]. Similar, but less detailed information, for SRS was also presented [SSM PEIS, Vol. II, Sec. A.1.2, p. A-10]. Appendix A also discussed the specific facilities anticipated to be used for pit fabrication at LANL [SSM PEIS, Vol. II, Sec. A.3.3.1, p. A-117]; a list of specific facilities (including CMR and Sigma at TA-3, and the Plutonium Facility (PF) 4 and Nuclear Materials Storage Facility (NMSF) at TA-55) and type of construction was provided [SSM PEIS, Vol. II, Table A.3.3.1-1]. The text pointed out that if LANL were selected as the pit fabrication site, the then-current stockpile pit rebuild program at LANL would be absorbed within the pit fabrication effort since the activity would be the same -- only the number of pits would be different (greater) [SSM PEIS Vol. II, p. A-120]. Similar information was provided for SRS [SSM PEIS Vol. II, Sec. A.3.3.2, p. A-124].

In December 1996 DOE issued its programmatic decisions regarding how it would implement the SSM Program. The SSM ROD was based on more than just the environmental analysis of the SSM PEIS. DOE considered "other factors such as DOE statutory mission requirements, national security policy, cost, schedule, and technical risks. Additional technical descriptions and assessments of cost, schedule and technical risk are found in the Analysis of Stockpile Management Alternatives (DOE/AL, July 1996), the Stockpile Management Preferred Alternatives Report (DOE/AL, July 1996) ..." [SSM ROD, Supplementary Information - Background]. The technical and cost analyses for production capability and capacity alternatives analyzed in the SSM PEIS were covered in the draft "Stockpile Management Preferred Alternatives Report" [A.R. No. I-1381] and the "Analysis of Stockpile Management Alternatives" [A.R. No. I-1381], both dated February 1996, mentioned in the Final SSM PEIS [see, for example, SSM PEIS Vol. IV, comment response 40.18, p. 3-107]. The analyses in these reports showed that compared to SRS, locating the pit fabrication mission at LANL would be lower in cost and have less technical risk because LANL had recent experience in providing pits for nuclear explosive testing [SSM PEIS Vol. IV, comment response 32.03, p. 3-81; 32.06, p. 3-81]. These draft reports mentioned in the SSM PEIS were released in final form in July 1996 [A.R. No. I-1506] following the SSM PEIS and were used by the decisionmaker in determining SSM Program implementation decisions.

The DOE SSM decision regarding reestablishing pit fabrication was:

> ...to reestablish the pit fabrication capability, at a small capacity, at LANL. ... This decision limits the plutonium fabrication facility plans to a facility sized to meet expected programmatic requirements over the next ten or more years. It is not sized to have sufficient capacity to remanufacture new plutonium pits at the same production rate as that of their original manufacture. DOE will perform development and demonstration work at its operating plutonium facilities over the next several years to study alternative facility concepts for larger capacity. Environmental analysis of this larger capacity has not been performed at this time because of the uncertainty in the need for such capacity and the uncertainty in the facility technology that would be utilized. Should a larger pit fabrication capacity be required in the future, appropriate environmental and siting analysis would be performed at that time.
>
> Mitigation. Specific mitigation measures are not addressed for the stockpile management decisions of the ROD, although many potential mitigation measures are identified in the PEIS. In accordance with the Stockpile Stewardship and Management Program's two-tiered NEPA Strategy, these specific mitigation measures will be addressed, as necessary, on a site-by-site basis, in any site-specific NEPA analyses needed to implement the stockpile management decisions of this ROD.
>
> [ROD, Sec. 3.A.4]

In May 1997, a coalition of 39 organizations headed by the Natural Resources Defense Council (NRDC) brought action against DOE for alleged failure, among other things, "to adequately analyze the environmental effects of, and reasonable alternatives to" the SSM Program [NRDC v. Peña, Complaint for Declaratory and Injunctive Relief, May 2, 1997, p. 7]. In an amended complaint plaintiffs brought action against DOE for alleged failure, among other things, "to prepare a Supplemental [PEIS] based upon significant new information regarding the potential environmental impacts arising from ... the fabrication of nuclear weapon cores, or pits, at [LANL]"

[NRDC v. Peña, Amended Complaint for Declaratory and Injunctive Relief, January 30, 1998, p. 6 - 7]. The amended complaint included an affidavit from NRDC researcher Christopher Paine (Paine Affidavit) dated January 30, 1998, which among other things gave five reasons why plaintiffs believe a supplemental SSM PEIS was needed to further address pit production at LANL.

RECENT ISSUES RELATED TO PIT PRODUCTION

Overview

This Supplement Analysis has been prepared to determine whether to supplement that portion of the SSM PEIS which deals with the proposed action to reestablish a manufacturing capability and capacity for pits. It specifically looks at the five points raised by the Paine Affidavit, which are alleged to warrant preparation of a supplemental SSM PEIS. It also examines four issues which were raised by DOE because they may have some bearing on addressing points raised by Paine. The following section describes the issues raised by plaintiffs and by DOE.

Issues Raised by Plaintiff NRDC et al.

The Amended Complaint of January 30, 1998, among other things, asks that a supplemental SSM PEIS be prepared to address pit production at LANL. Reference is made to PF-4, TA-55, which is the main plutonium processing facility at LANL, the CMR Building at TA-3, and NMSF at TA-55. The following five issues and claims of alleged new information regarding DOE's pit production mission at LANL were identified by plaintiffs NRDC, et al., in their amended complaint and accompanying memorandum and supporting documents.

1. **Impacts at TA-55, PF-4.** That all proposed activities analyzed in the SSM PEIS for the LANL pit production mission were assumed to take place at TA-55, PF-4, and that impacts from connected actions were omitted. (Plaintiffs' Memorandum of Points and Authorities, Ex. 1, Affidavit of Christopher Paine, paragraph 19.)

2. **Connected actions.** That the Final PEIS did not identify and assess the connected and cumulative environmental impacts of six projects related to pit production, costing on the order of $1 billion. Those six projects are:
   (a) Modernize facilities and infrastructure at TA-55, particularly PF-4, to allow the continuing safe nuclear materials processing operations needed for pit fabrication through FY 2020.
   (b) Modernize the facilities and infrastructure of the TA-3 Sigma Complex for fabricating nonnuclear (e.g. beryllium, vanadium, uranium) pit components.
   (c) Relocate selected environmentally sensitive nuclear materials missions from TA-55 to CMR to provide sufficient space for expanded pit manufacturing operations at TA-55, a decision that is now under active reconsideration and may be abandoned.
   (d) Add sufficient analytical chemistry to the CMR facility to support increased pit production rates.
   (e) Establish a Special Nuclear Material Transportation Corridor between TA-55 and the CMR facility.
   (f) Renovate NMSF to accommodate increased plutonium inventory resulting from a planned increase in pit surveillance and pit fabrication operations.

   (Plaintiffs' Memorandum of Points and Authorities, Ex. 1, Affidavit of Christopher Paine, paragraph 20.)

3. **Surge planning scenario.** That the PEIS analysis is outdated because it did not analyze the reasonable foreseeable environmental impacts from DOE's approved surge planning scenario for fabricating up to 500 pits per year at multiple sites. (Plaintiffs' Memorandum of Points and Authorities, Ex. 1, Affidavit of Christopher Paine, paragraph 21.)

4. **DNFSB safety consideration.** That the PEIS inadequately considered safety consideration associated with the CMR Building, identified in part in a December 1997 DNFSB report to DOE. (Plaintiffs' Memorandum of Points and Authorities, Ex. 1, Affidavit of Christopher Paine, paragraphs 22 and 23.)

5. **Accidents involving Pu-238.** That the PEIS omitted any analysis of accident consequences involving release of Pu-238, where information indicates that two-thirds of the PF-4 space at TA-55 slated for processing Pu-238 would be located in the same building as pit fabrication activities. (Plaintiffs' Memorandum of Points and Authorities, Ex. 1, Affidavit of Christopher Paine, paragraph 24.)

Issues Raised by DOE

The SSM ROD assigned the mission to reestablish its pit fabrication capability, at a small capacity, at LANL. DOE's plans for implementing the pit production mission at LANL have evolved, organizational changes have been accomplished, and new studies have been initiated regarding regional environmental features. The pertinent issues that have been raised by DOE over the past several months, which bear on the issues raised by plaintiffs, are as follows.

1. **Pit production strategy.** That DOE approved a modified strategy for pit fabrication in December 1997 and in January 1998 directed LANL to pursue the modified strategy. The strategy in general addressed engineering project management, scheduling, and logistics issues. The three objectives of the new strategy are:

   (a) Decouple the specific DOE project for pit fabrication, which is included in the Capability Maintenance and Improvements Project (CMIP), from other projects and focus development of pit production capability at TA-55 without disrupting ongoing mission.
   (b) Maintain pit production as a continuous process, and achieve an intermediate capacity of 20 pits per year by FY 2007 without prejudice to the eventual 50 pit per year capacity.
   (c) Delay CMIP while performing urgent maintenance and equipment replacement beginning in FY 1999.

2. **CMR project management considerations.** That in early 1997 DOE and LANL decided to temporarily suspend construction activities for the CMR upgrades project pending a thorough budget and project management review.

3. **CMR safety reviews and organizational changes.** That on September 2, 1997, in response to safety considerations, LANL temporarily suspended operations within the CMR building pending an in-depth review of all operations and procedures being implemented within the building to support on-going LANL missions. Operations were resumed over time in a phased manner as work control and work authorization procedures were verified for each on-going project within the building.

4. **New earthquake faulting studies at LANL.** That new studies initiated in 1997 indicate an increased likelihood of geologic rupture should certain seismic events occur.

ANALYSIS OF ENVIRONMENTAL ISSUES RAISED

Analysis

For each of the issues outlined above, this Supplement Analysis examines the following factors:

(a) Is the issue germane to a NEPA analysis?
(b) Does the issue represent a substantial change to the proposal analyzed in the SSM PEIS?

(c) Does the issue present significant new circumstances or information relevant to environmental concerns that was not available to the decisionmaker at the time the SSM ROD was issued?
(d) Would the issue, if known at the time, have affected the outcome of the programmatic decisions in the SSM ROD?

If the Supplement Analysis leads to the conclusion that the decisions in the SSM ROD were based on an obsolete analysis, and if new information could have led to a different programmatic decision regarding where to locate the reestablished pit fabrication capability, then the SSM PEIS should be supplemented. If the Supplement Analysis leads to the conclusion that the information raised in the issue was incorporated in the SSM PEIS or otherwise known to the decisionmaker at the time the SSM ROD was issued; that the information pertains to site-specific implementation of programmatic decisions; or that the information is irrelevant to a NEPA review; then the SSM PEIS need not be supplemented.

Analysis of Issues Raised by Plaintiffs

1. Impacts at TA-55, PF-4. That all proposed activities analyzed in the SSM PEIS for the LANL pit production mission were assumed to take place at TA-55, PF-4, and that impacts from connected actions were omitted.

The alternative to reestablish pit fabrication at LANL is discussed in the SSM PEIS in Chapter 3 [SSM PEIS Vol. I, Sec. 3.4.3.2, p. 3-58] which in turn refers to a more detailed discussion in Appendix A [SSM PEIS Vol. II, Appendix A, Sec. A.3.3.1, p. A-117]. Appendix A, Table A.3.3.1-1, lists six separate buildings projected to be used for pit fabrication if the mission were located at LANL. Therefore it was understood that more than one facility would be used for pit fabrication activities at LANL. [See also the *Declaration of Paul T. Cunningham*, June 6, 1997, paragraph 5.]

The SSM PEIS provided an analysis of those factors that allowed the decisionmaker to discriminate between locating the pit fabrication capability at LANL or SRS. The SSM PEIS focused on major facilities and omitted minor facilities [SSM PEIS, Vol. II, Sec. A.1.5, p. A-28]. The programmatic analysis was based on bounding scenarios for potential impacts at the two sites considered, and the level of detail that appeared in the SSM PEIS was sufficient for the decision to be made -- that of placement of mission.

Environmental impacts from reestablishing pit fabrication at LANL were analyzed in Chapter 4 [SSM PEIS, Vol. I, Sec. 4.6.3, p. 4-276]; impacts to the several facets of the environment were projected based on the description of the alternatives in Appendix A. The discussions under many of the facets made reference to the multiple TAs involved in the proposal; see, for example, the discussion for cultural resources [SSM PEIS, Vol. I, Sec. 4.6.3.7, p. 4-291] which specifically addressed the potential for impacts at each of six TAs. The Paine Affidavit issue specifically addressed impacts for waste management, air quality, and surface water. The PEIS impact analysis for waste management referenced LANL "facilities" in the plural [SSM PEIS, Vol. I, Sec. 3.4.3.2, p. 3-61]; that for air quality was based on either actual stacks or a hypothetical centrally located stack [SSM PEIS, Vol. II, Sec. B.3.6, p. B-14]; that for surface water resources referenced "TAs" in the plural [SSM PEIS, Vol. I, Sec. 4.6.3.4, p. 4-283]. Therefore, where appropriate impacts were analyzed for more than just TA-55.

The SSM PEIS provided a comparative analysis of the action alternatives against the No Action alternative, which served as a reference base [SSM PEIS, Vol. II, Sec. A.1, p. A-1]. Each of the two sites analyzed in the SSM PEIS, LANL and SRS, have an existing infrastructure associated with nuclear operations; hence the impacts associated *with locating the pit fabrication mission were additive to the No Action impacts from missions already* at each site. The No Action alternative assumed that the sites would continue to operate until at least 2005 with existing facilities that could comply with environment, safety and health requirements, and that facilities would be subject to routine maintenance and repairs. Therefore, the impacts of reasonably foreseeable facility repairs and workloads were included in the No Action baseline.

Consideration of whether actions are connected in the sense of NEPA is useful to determine whether they should be analyzed together, as in a programmatic review such as the SSM PEIS, rather than separately [40 CFR 1508.25(a)(1)]; it is appropriate to consider in one programmatic analysis the impacts from establishing connected pit fabrication activities in several facilities. The SSM PEIS did this. In keeping with the two-tiered NEPA strategy outlined in the SSM PEIS [SSM PEIS, Vol. I, Sec. 1.5, p.1-8], DOE decided that the impacts of implementing programmatic decisions at a site-specific level would be addressed in subsequent tiered project-specific NEPA reviews [SSM ROD Sec. 3.A.4].

The LANL Site Wide EIS (SWEIS), currently in preparation in accordance with 10 CFR 1021.330(c), will provide a site-specific look at the cumulative impacts of operating LANL; it will also analyze four alternative ways to continue to operate the entire site for the next ten years [Advance Notice of Intent (ANOI) to prepare the SWEIS [59 FR 40889, August 10, 1994], A.R. No. VII.B-14; Notice of Intent to prepare the SWEIS [60 FR 25697, May 12, 1995], A.R. No. VII.B-18; LANL SWEIS Implementation Plan [DOE/EIS-0238], November 1995, A.R. No. VII.B-20]. The four planned draft alternatives are:

(a) No Action - continue LANL operations at their current planned level.
(b) Expanded Operations - implement all current DOE mission element assignments to LANL at the highest foreseeable level of activity and fully implement recent mission assignments.
(c) Reduced Operations - conduct the minimal level of activity necessary to maintain capabilities necessary to support DOE missions.
(d) Greener Operations - use LANL capabilities to minimize support to DOE defense and nuclear weapons missions, and maximize support to other DOE mission elements.

The LANL SWEIS will consider the impacts of implementing the SSM programmatic decisions at LANL. It will consider enhancement of the existing pit manufacturing capability at LANL, and is expected to provide a project-specific NEPA review for certain aspects of the SSM ROD pit fabrication mission assignment, including CMIP. The SSM PEIS looked at pit fabrication needs over the next 10 or more years, essentially the same timeframe as the LANL SWEIS analysis. Under the No Action Alternative (the base case in the SWEIS analysis), LANL could continue to fabricate pits at the existing capability level (approximately a pit per month); under the Expanded Operations alternative, LANL could fabricate 50 pits per year (using a single labor shift) or achieve 80 pits per year (the surge level indicated in the SSM PEIS) within the 10-year timeframe; and under the other two alternatives LANL could maintain a pit manufacturing capability but produce pits at a lesser number.

The Draft LANL SWEIS is currently scheduled for release to the public for review and comment in May 1998. The Final SWEIS is scheduled for November 1998, and the ROD for late 1998.

The issue is in error regarding the allegation that only TA-55 was considered in the SSM PEIS; the SSM PEIS analysis was based on the projection that several major and minor facilities at LANL would be involved in pit fabrication. The issue provides no new information that was not available to the SSM decisionmaker. Therefore, no change to the SSM PEIS is warranted.

2. Connected actions. That the Final PEIS did not identify and assess the connected and cumulative environmental impacts of six projects related to pit production, costing on the order of $1 billion. Those six projects are:

(a) modernize facilities and infrastructure at TA-55, particularly plutonium Facility 4, to allow the continuing safe nuclear materials processing operations needed for pit fabrication through FY 2020;

The SSM PEIS limited its review of alternative locations for reestablishing pit fabrication to those sites that already had some measure of the appropriate technical or facility infrastructure [SSM PEIS Vol. I, Sec. 2.5.3, p. 2-11];

only two sites, LANL and SRS, qualified. At LANL the preexisting plutonium capability existed largely at TA-55, which contributed to LANL qualifying as an alternative site. Facilities at LANL such as TA-55 are used to support a variety of mission needs for a variety of sponsors [SSM PEIS Vol. I, Sec. 3.2.6, p. 3-18; Table 3.2.6-1, p. 3-19]. TA-55 is one of the newer facilities at LANL (first occupied in the late 1970s); like all buildings it requires periodic maintenance in order to continue to operate. The SSM PEIS indicated that no facilities at LANL would be phased out regardless of decisions on pit fabrication stemming from the SSM PEIS [SSM PEIS Vol. I, Sec. 4.6.1, p. 4-246]. It is essential to maintain the nuclear infrastructure at LANL in safe operating condition and perform upgrades when necessary to achieve environment, safety and health goals. Therefore, the SSM PEIS decisionmaker was aware that DOE would be obligated to repair and maintain its facilities at LANL, including TA-55, in a safe operating condition independent of the mission assignment for pit fabrication. LANL has existing capabilities that are essential to support other ongoing missions in addition to pit fabrication, such as the TA-55 capability for residue processing and for storing and handling plutonium. Although TA-55 facilities are being used to support LANL's pit fabrication mission, facility maintenance requirements exist independent of this mission assignment.

DOE included requirements and plans for refurbishing nuclear facilities at LANL as part of the No Action alternative in the SSM PEIS. In addition, this issue was addressed in the Final PEIS Comment Response Document [SSM PEIS, Vol. IV]. In response to a question of why DOE is investing in new facilities at LANL, DOE stated that "The TA-55 plutonium facility is approaching 20 years of service and many components of the facility need replacement or upgrading in order to sustain the R&D mission of the laboratory." [SSM PEIS Vol. IV, comment response 32.16, p. 3-84.] DOE further stated: "It is true that DOE has determined that, under the existing stockpile stewardship and management activities that have been ongoing for many years, facilities at LANL will have to be maintained and in some cases repaired or upgraded to allow LANL to continue to fulfill its existing mission. Far from being a 'stunning admission' that future assignments are already being implemented, DOE believes that is simply good management practice to keep its considerable real property -- its buildings and other infrastructure -- in safe, sound, and operating order." [SSM PEIS, Vol. II, comment response 40.90, p. 3-144.] DOE and LANL need to continue to operate TA-55 and PF-4 in a way that will allow the safe operation of the buildings to support nuclear materials processing operations for the indefinite, foreseeable future; one such use, but not the only such use, will be pit fabrication activities. In addition to the repairs and maintenance that would take place under the No Action baseline, the SSM PEIS acknowledged that upgrades to PF-4, TA-55 would be needed to implement the pit fabrication mission [SSM PEIS, Vol. I, Sec. 3.4.3.2, p. 3-58].

The SSM PEIS provided a programmatic review of the factors needed for the decisionmaker to discriminate between locating the pit fabrication activities at LANL or SRS. Under the two-phase NEPA strategy outlined in the SSM PEIS, project-specific decisions related to exactly how the programmatic decisions would be implemented at LANL would be covered in subsequent tiered NEPA reviews. Although the SSM PEIS indicated it assumed, as a No Action base case, that operating facilities at LANL and SRS would be kept in safe, environmentally compliant operating condition [SSM PEIS, Vol. II, Sec. A.1, p. A-1], it did not analyze at the site-specific level exactly how that would be accomplished. That level of detail would have been unnecessary, hence inappropriate, for a programmatic siting decision. Any future proposals to upgrade equipment or structures at TA-55 would be looked at to determine if they would be subject to NEPA review; any such review pertaining to pit fabrication would be considered a tiered review flowing from the SSM PEIS and ROD. This issue was also addressed in November 1997 as part of the court-ordered disclosure of information regarding pit production activities at LANL.

The Paine Affidavit makes reference to a newspaper article about the pit fabrication project (Paragraph 20, Attachment G), "LANL Plutonium Pit Project Plagued by Cost Overruns" [*Santa Fe New Mexican*, December 5, 1997, p. A-1, A.R. VII.B-44]. This article was based on a wide-ranging interview with the LANL pit fabrication program manager, and discussed the then-current status of the pit fabrication project. The article discussed cost overruns in the CMR Upgrades project. The situation regarding cost overruns in the CMR Upgrades project is addressed under DOE Issue 2, below. The article also referenced five upgrade alternatives; these are discussed below under Plaintiffs' Issue 5, Paine Affidavit Attachment J. The information referenced in the newspaper article does not constitute a substantial change to the programmatic proposal analyzed in the SSM PEIS.

This issue is not germane to a programmatic decision as to whether to site pit fabrication capabilities at LANL or SRS. Because it was understood in the SSM PEIS that facilities such as TA-55 needed to be kept in safe operating condition regardless of whether or not LANL received the pit fabrication mission, this issue does not present new information that was not available to the SSM decisionmaker. Even if a NEPA review would be required, it would be a tiered, project-specific review. Therefore, no change to the SSM PEIS is warranted.

(b) modernize the facilities and infrastructure of the TA-3 Sigma Complex for fabricating nonnuclear (e.g. beryllium, vanadium, uranium) pit components;

Nonnuclear weapons components such as those made from beryllium are an integral part of a pit; fabricating beryllium and other components was reassigned to LANL in 1993 prior to and independently of the pit fabrication mission assignment [SSM PEIS Vol. IV, comment response 32.08, p. 3-83]. In 1992 DOE decided to prepare an Environmental Assessment (EA) on its proposal to consolidate certain nonnuclear facilities within the nuclear weapons complex [57 FR 3046, January 27, 1992, A.R. No. VII.B-5], and completed the EA in June 1993 [DOE/EA-0792, A.R. No. III-85]. In this context, nonnuclear facilities are those which manufacture or test the nonnuclear parts of nuclear weapons. These parts include such things as electronics, batteries, detonators, and specifically include beryllium technology and pit support [Nonnuclear Consolidation EA Executive Summary, p. ES-1, DOE/EA-0792(ES), A.R. No. VII.B-9]. On September 14, 1993, DOE issued a Finding of No Significant Impact (FONSI) on the Nonnuclear Consolidation EA [58 FR 48043, A.R. No. VII.B-12] after considering public comments on a proposed FONSI [A.R. No. VII.B-11]. The then-proposed action included a proposal to enhance existing beryllium technology at LANL: "Beryllium Technology and Pit Support -- The existing technology base and prototyping capability at LANL would be enhanced to provide limited manufacturing capability for beryllium technology and pit support now done at RFP." [58 FR 48045.]

As soon as the FONSI was issued, DOE began to implement the proposed action [Letter from Howard Canter, Deputy Assistant Secretary for Weapons Complex Reconfiguration, to Interested Parties, September 24, 1993, A.R. No. VII.B-13]. The beryllium technology work from RFP was subsequently moved to the Sigma Complex at TA-3, LANL, to complement and enhance the prior existing capability.

The DOE's proposal to enhance the capability at the TA-3 Sigma Complex for beryllium technology and pit support functions was analyzed at length in the Nonnuclear Consolidation EA, June 1993, and discussed in its FONSI, September 1993. Implementation of this proposal began shortly after the FONSI was issued and included upgrades to Sigma Complex. Therefore, this decision did not have to be revisited in the SSM PEIS; since no decisions were needed on this aspect, no additional NEPA analysis was needed in the SSM PEIS.

This issue does not present new information that was not available to the SSM decisionmaker. Therefore, no change to the SSM PEIS is warranted.

(c) relocate selected environmentally sensitive nuclear materials missions from TA-55 to the aging CMR building to provide sufficient space for expanded pit manufacturing operations at TA-55, a decision that is now under active reconsideration and may be abandoned;

The SSM PEIS addressed the programmatic issues related to whether to site pit fabrication activities at LANL or SRS. The SSM PEIS stated that site-specific implementation of the programmatic decision would be addressed in subsequent tiered NEPA reviews [SSM PEIS, Vol. I, Sec. 1.5, p. 1-8]. The CMR Building is needed to support ongoing LANL work regardless of the assignment of the pit fabrication mission to LANL, and space allocations for assignment of work relating to nuclear materials may or may not be relevant to the pit fabrication mission. For pit fabrication, the specifics of exactly what processes would go in which building would be a site-specific detail of implementation beyond the intent of the SSM PEIS. A planning decision has not yet been made regarding whether to propose the use of the CMR building for missions relocated from TA-55, if, in fact, any activities are moved from TA-55. Potential environmental impacts for this scenario, if proposed, would be analyzed in project-specific NEPA reviews when appropriate. Alternatives to moving activities from TA-55 to CMR are anticipated to be addressed in the LANL SWEIS, including the potential for expanding TA-55. In the event that a decision that is made through a NEPA review is subsequently abandoned, additional NEPA review is not needed to address the agency's failure to take the action.

This issue does not present new information that is germane to a programmatic SSM decision. Therefore, no change to the SSM PEIS is warranted.

(d) add sufficient analytical chemistry capacity to the CMR facility to support increased pit production rates;

LANL has existing capabilities that are essential to support other ongoing missions in addition to pit fabrication including the capability for analytical chemistry in CMR. In 1997 DOE completed its EA on the proposed upgrades to the CMR Building [DOE/EA-1101, A.R. No. VII.B-27]. DOE found that no significant impacts would be expected to occur, therefore an EIS on that proposal was not needed [FONSI, February 11, 1997, A.R. No. VII.B-28]. The EA analyzed upgrades needed to make the building continue to be useable for the foreseeable future for continuing ongoing mission assignments. It specifically did not analyze upgrades needed to implement potential future new mission assignments. The CMR FONSI covered two potential upgrade designs for the CMR upgrades. Under the first, DOE would upgrade the chemistry space in three wings with collocated office space. Under the second, DOE would upgrade the chemistry space in two wings, relocate office space, and put the third wing in safe standby condition. The FONSI stated that if DOE selected the second design, and subsequently considered the space in the third wing for other programmatic needs, DOE would perform a separate NEPA analysis regarding any proposed new mission use.

DOE must maintain the nuclear infrastructure at LANL regardless of the pit fabrication mission in order to perform nuclear operations safely and reliably. Analytical chemistry is needed to support pit fabrication [SSM PEIS, Vol. I, Sec. 3.4.3.2, p. 3-58; Sec. 3.4.3.3, p. 3-64]. The SSM PEIS analyzed analytical chemistry as part of the infrastructure capability for each site (LANL and SRS) sufficient to support the pit capacities analyzed. The CMR building, built in the early 1950s, requires maintenance, repairs and upgrades to sustain the effectiveness and safety of the facility. These upgrades were addressed in the No Action Alternative in the SSM PEIS [SSM PEIS, Vol. IV, comment response 41.18, p. 3-158] and in the CMR EA and FONSI of February 1997. [See also the Declaration of Paul T. Cunningham, paragraphs 9 and 10, and the Second Declaration of Albert E. Whiteman, paragraph 5.d.1.]

There are no proposals to increase pit production rates over those analyzed in the SSM PEIS. Although at the request of Congress DOE and LANL have done some preliminary contingency planning as to how higher production rates might be achieved, if ever necessary, these considerations have not reached the state of an agency proposal, hence are not ripe for decision or NEPA review (see Plaintiffs' Issue 3, below).

This issue is based on incorrect information regarding rates of pit fabrication. The issue does not indicate that the analytical capability analyzed in the PEIS was incorrect. Therefore, no change to the SSM PEIS is warranted.

(e) establish a Special Nuclear Material Transportation Corridor between TA-55 and the CMR facility;

Although the idea of paving an existing, essentially abandoned, gravel road between TA-55 and the CMR Building at TA-3 has been discussed over the years, and may have some advantages for the safe, secure transport of nuclear materials between those two facilities, DOE has not yet formally proposed to undertake this action; however, it is anticipated that this may be included in the SWEIS as part of the consideration of a possible new transportation corridor between the two buildings.

This issue is not germane to a programmatic NEPA review since it is at the level of a minor site-specific infrastructure feature. While it may be a convenience in operating LANL facilities, it is not a necessary action for pit fabrication and does not bear on the programmatic decision to locate the pit fabrication mission at LANL. Therefore, no change to the SSM PEIS is warranted.

(f) renovate and make major modifications to the Nuclear Materials Storage Facility (NMSF) at TA-55 to accommodate increased plutonium inventory resulting from planned increase in pit surveillance and pit fabrication operations.

In 1986 DOE completed an EA and FONSI on the construction and operation of the then-new proposal for NMSF. [Memorandum, DOE/HQ, EH-1, Assistant Secretary Walker, to DOE/HQ, DP-1, Assistant Secretary Foley, August 28, 1986, A.R. VII.B-2; NMSF EA, A.R. No. VII.B-1, and FONSI, August, 1986, A.R. No. VII.B-2.] The operation of NMSF for its intended purpose was considered in the SSM PEIS as part of the No Action baseline and as a facility that could be used to support pit fabrication at LANL.

The NMSF was conceived in the early 1980's as a centralized facility at LANL for receipt and intermediate to long-term storage of special nuclear materials. Upon completion of construction of NMSF in 1987, DOE and LANL identified design and construction deficiencies in this facility which precluded the acceptance of the structure for occupancy; the introduction of nuclear materials into the NMSF was therefore not possible because it could not be used for its intended function and because health and safety operating parameters could not be met. In the early 1990's a series of studies was conducted to determine what needed to be done to bring the structure to an operable state. The repairs came to be known as the "NMSF Renovation Project." The NMSF renovations would allow the building to operate at its original design capacity (6.6 metric tons of plutonium) to support ongoing mission assignments at LANL, and were determined to be covered by the 1986 NMSF EA [Memorandum, Webb, DOE/LAAO, to Foxx, LANL, December 21, 1994, A.R. VII.B-17; covering memorandum, Reis, DOE/HQ/DP-1, to Manager, DOE/AL, November 9, 1994, A.R. No. VII.B-15; see also Ellard, LANL, May 14, 1993, A.R. No. VII.B-6, and Tingley et al., LANL, May 25, 1993, A.R. No. VII.B-7].

DOE is now renovating the facility to correct design and construction deficiencies in the structure, and damage and deterioration resulting from these deficiencies. Conceptual design for the NMSF renovations began in 1997, preliminary design began in 1998, final design is expected to start in the spring of 1999, construction is scheduled to begin in the summer of 2000, and the renovations are scheduled to be completed in 2004. The renovations will allow the facility to store up to 6.6 metric tons of plutonium, as was covered in the 1986 EA and FONSI. The facility will be used to support many on-going LANL mission requirements, including the SSM Program.

DOE plans to renovate the NMSF, as has been discussed since 1992, to correct design and construction deficiencies in the structure and damage and deterioration resulting from these deficiencies. However, the renovations would serve only to make the building functional in order to perform the activities discussed and analyzed in the 1986 NMSF EA and FONSI. The baseline used in the SSM PEIS for determining the impacts of reestablishing pit fabrication capability at LANL included making use of NMSF when functional (NMSF cannot be used to store nuclear materials until it becomes functional which would not be possible until renovation activities have taken place). The plans to renovate the NMSF were known to the SSM decisionmaker and do not constitute new information. There are no plans to store additional material in the NMSF over the amount considered at the time the SSM PEIS was prepared -- the NMSF will be renovated to accommodate storing 6.6 metric tons of plutonium, the same amount of material used as the basis of the analysis in the 1986 NMSF EA.

There are no proposals to increase pit production rates over those analyzed in the SSM PEIS. Although at the request of Congress DOE and LANL have done some preliminary contingency planning as to how higher production rates might be achieved, if ever necessary, these considerations have not reached the state of an agency proposal, hence are not ripe for decision or NEPA review (see Plaintiffs' Issue 3, below). There are no plans to increase pit surveillance over current projections (known to SSM decisionmakers) or to increase pit fabrication operations over the levels analyzed in the SSM PEIS.

This issue was earlier addressed in this litigation in the First Declaration of Albert E. Whiteman. He states that the NMSF renovation was considered in the baseline No Action alternative of the SSM PEIS, and that these "activities are necessary for ongoing stockpile stewardship and management independent of the determination made in the SSM-PEIS." [First Declaration of Albert E. Whiteman, p. 2. See also Declaration of Paul T. Cunningham, paragraph 11.]

This issue does not present new information that was not available to the SSM decisionmaker. The issue regarding increase in pit fabrication operations over that analyzed in the SSM PEIS is erroneous. Therefore, no change to the SSM PEIS is warranted.

3. Surge planning scenario. That the PEIS analysis is outdated because it did not analyze the reasonable foreseeable environmental impacts from DOE's approved surge planning scenario for fabricating up to 500 pits per year at multiple sites.

The SSM PEIS analysis of fabricating 20 to 50 pits per year, with 80 pits per year on a surge basis, was predicated on the need for new pits over the next 10 or more years. For comparison, the capacity of RFP when operating was about 2,000 pits per year [SSM PEIS Vol. IV, comment response 32.01, p. 3-80]; the SSM PEIS addressed reestablishing the former RFP capability but not its former capacity. DOE was aware at the time the PEIS was prepared that future requirements for capacity for pit fabrication were uncertain [*SSM PEIS Vol. I, Sec. 3.6, p.* 3-93]. In the SSM PEIS Comment Response Document, DOE stated: "Because of the small demand for the fabrication of replacement plutonium pits over the next 10 or more years, DOE did not propose a new pit fabrication facility with a capacity equivalent to the capacities required for other portions for the nuclear weapons complex. However, limited fabrication of new replacement pits would be required to maintain capability and to replace pits lost during weapons surveillance. Section 3.6 discusses DOE's future plans should a life-limited phenomenon be found in stockpile pits and a larger pit fabrication capacity be required." [SSM PEIS Vol. IV, comment response 40.19, p. 3-107.] The SSM ROD indicated that if a greater capacity for pit fabrication were to be needed in the future, appropriate environmental and siting analyses would be performed at that time [SSM ROD Supplementary Information; Sec. 3.A.4]. To date, the nation has not determined future stockpile rates to be greater than anticipated in the SSM PEIS, and DOE has no proposals at this time to establish a greater pit fabrication capacity within its planned capability.

Part of the assignment given to LANL by the SSM ROD was to assist DOE in developing equipment and technologies to expand the limited capability assigned in 1996 to LANL into a larger capability that might be needed by DOE at some site at some point in the future. This did not imply that such an expanded capacity, if ever needed, would be located at LANL; instead, the SSM ROD stated that in this event, environmental and siting studies would be performed [SSM ROD 3.A.4].

The Paine Affidavit makes reference to LANL's Institutional Plan for FY 1998 - 2003 (Paragraph 21, Attachment H). The "Institutional Plan FY 1998 - FY 2003" [LALP-97-130, October 1997, A.R. No. VII.B-40], in turn, makes reference to a multi-site study and the consideration of a modular production capability that could be deployed rapidly if there was a change from the requirements considered in the SSM PEIS and ROD [LALP-97-*130, p. 28]. In February 1996 DOE formed an inter-site team which was asked to develop a plan which would* provide a strategy to establish a project in FY00 which would be responsible for developing a means to achieve a higher pit production capacity within five years of an identified need [Memorandum, February 21, 1996, Whiteman to Veldman, et al., A.R. No. VII.B-22; Attachment, "Rapid Reconstitution of Pit Production Capacity," February 20, 1996, Khalil, DOE AL, A.R. No. VII.B-21]. The memorandum stated that the project needed to provide a scaleable capacity, and would require development and technology demonstration; the *SSM ROD* subsequently recognized this: "DOE will perform development and demonstration work at its operating plutonium facilities over the next several years to study alternative facility concepts for a larger capacity." [SSM ROD, Sec. 3.A.4.] This memorandum predated the SSM PEIS and was known to the SSM decisionmaker. In August 1997 the inter-site team completed its report, "Rapid Reconstitution of Pit Production Capacity: Systems Studies Assessment and Recommendations" [LLNL UCRL-ID-128655, Jardine, LLNL, Reardon, LANL, and Grimley and Branstetter, Sandia National Laboratories, August 1997, A.R. No. VII.B-36]. This document is subject to controlled distribution because it contains Unclassified Controlled Nuclear Information (UCNI) material. The strategy responds to the 1996 memorandum charge to be able to establish a greater capacity within five years of an identified need. The SSM ROD stated that in the event a larger capacity were ever needed, appropriate siting and environmental reviews would be performed at that time [SSM ROD, Sec. 3.A.4]. While the August 1997 report was completed after the SSM ROD was issued, it addressed a topic that the SSM ROD specifically excluded as a reasonably foreseeable action requiring a programmatic decision at that time. Therefore neither the LANL Institutional Plan nor the 1997 rapid reconstitution plan present new information that would bear on the SSM ROD decisions to site pit manufacturing capacity at LANL.

As part of prudent planning to support and maintain the directed stockpile levels in the event of an unforeseen future issue that could affect national security, at the request of Congress in FY96 DOE began work on a preliminary contingency plan that could put into place a production capability of up to 500 pits per year. In the National Defense Authorization Act for Fiscal Year 1997, P.L. 104-201, Section 3151, Congress required the Secretary of Energy to submit to Congress a report on DOE's plans for achieving the capability to produce and remanufacture plutonium pits. In response to that requirement, DOE prepared the "Department of Energy Report on Plutonium Pit Production and Remanufacturing Plans" [Letter, Secretary Peña to Congressman Floyd Spence, Chairman, Committee on National Security, U.S. House of Representatives, August 18, 1997, covering "Department of Energy Report on Plutonium Pit Production and Remanufacturing Plans, Secretary of Energy, July 1997." A.R. No. VII.B-37]. The report provided Congress with DOE's initial baseline plan to restore the capability to produce pits for the nuclear weapons stockpile (war-reserve pits). The baseline consisted of three parts: (a) demonstrate that the capability to produce war-reserve pits can be reestablished at LANL; (b) install a limited capacity at LANL to produce up to 50 war-reserve pits; and (c) develop a contingency plan to establish capacity to produce up to 500 war-reserve pits, using LANL technology as a model, at existing DOE buildings at SRS, DOE's Oak Ridge Reservation, DOE's Pantex Plant, and DOE's Nevada Test Site [Report, p. 2]. The number 500 was used for planning purposes because it represented a rate which could reproduce a large quantity "lot" within a reasonable timeframe, and because it was felt to be achievable by replicating multiple setups of the type that are being put into place at LANL. [See also A.R. No. VII.B-42.] No specific requirements for an upper capacity number have yet been developed. This preliminary plan, which has never progressed beyond its very early stages, is currently on hold pending development and evaluation of the design, processes, equipment, and feasibility of the current ongoing pit rebuild program at LANL. As stated in the SSM ROD, any decisions to pursue an expanded capacity in the future, including siting decisions, would be subject to further NEPA review [SSM PEIS, Vol. I, Sec. 1.5, p. 1-8].

The SSM PEIS and ROD acknowledged that future needs for pit fabrication capacity are unknown, and that future plans for future capacities will be subject to future NEPA review. The contingency plan requested by Congress, which has had some preliminary work, is not fully developed and is not expected to be fully developed for quite some time. Therefore it does not represent a proposal within the meaning of NEPA, and is not ripe for analysis or decision.

This issue does not present new information that is germane to the programmatic decisions in the SSM ROD. It raises an issue that is not yet ripe for NEPA review. Therefore, no change to the SSM PEIS is warranted.

4. DNFSB safety consideration. That the PEIS inadequately considered safety consideration associated with the CMR Building, identified in part in a December 1997 DNFSB report to DOE.

The DNFSB, established in 1988, has certain oversight responsibilities for nuclear facilities at LANL, such as TA-55 or CMR. Under its enabling statute [42 USC 2286] DNFSB is responsible for independent, external oversight of all activities in DOE's nuclear weapons complex affecting health and safety. The DNFSB reviews operations, practices, and occurrences at DOE's defense nuclear facilities and recommends actions to the Secretary of Energy to protect public health and safety. As such, the DNFSB assists DOE in its continuous efforts to control risks associated with its operations and to continually improve its performance. This aspect of site management is an integral component of continuing operations at all DOE sites, including LANL.

In July 1997 LANL provided DOE and the DNFSB with a copy of the draft "Enhanced Conceptual Design Report (ECDR) for the Capability Maintenance and Improvement Project (CMIP)" referenced in Paragraph 23 of the Paine Affidavit. The DNFSB conducted an on-site review of the draft ECDR in September 1997. The DNFSB letter of December 5, 1997, referenced in Paragraph 23 of the Paine Affidavit as Attachment I [A.R. No. VII.B-45], provided input to DOE and LANL on the draft ECDR. Completion of the draft ECDR is currently on hold due to project changes and funding considerations. DOE recently approved a modified approach to implementing CMIP [Memorandum, January 12, 1998, Whiteman to Cunningham, A.R. No. VII.B-50] (see DOE Issue 1), and the draft ECDR will be revised to accommodate the modified strategy. Given current funding and schedule considerations, LANL does not expect to resume work on the draft ECDR until FY99, with FY00 as the earliest completion date.

The issues raised by the DNFSB in its December 1997 letter are management and process issues consistent with the charter of that Board. While it is possible that future DOE initiatives associated with correcting the problems noted by the DNFSB could be subject to future NEPA reviews, no such proposals have yet been made. Furthermore, the management and process issues raised by the DNFSB do not affect the programmatic question of assignment of the pit production mission to either LANL or SRS addressed in the SSM ROD. Any proposals resulting from these issues will be appropriately addressed by further, facility-specific NEPA reviews.

CMR project management and operational considerations are discussed under DOE Issues 2 and 3. Construction of the CMR Upgrades project was temporarily suspended in the spring of 1997 pending review and implementation of better project management controls. That work was completed and construction restarted in the summer of 1997. Project management considerations of the Upgrades Project, CMR operations safety reviews and organizational changes are unrelated to NEPA reviews. In the fall of 1997 in response to safety considerations, LANL temporarily suspended operations within the CMR building pending an in-depth review of all CMR operations. Operations were resumed over time in a phased manner as work control and work authorization procedures were verified for each on-going project within the building; most operations have resumed. In November 1997, LANL received a new Director; in January 1998 the Director reorganized the management structure for operating the CMR Building and its ongoing operations. Budgeting, establishing project management controls, temporary suspension of work to review operational safety, and establishing management organizations would not be subject to NEPA. While it is possible that certain activities taken to improve operational safety may be subject to NEPA, any such action pertaining to implementing pit fabrication activities at LANL would be of a facility-specific nature; in other words, would be tiered from programmatic decisions established in the SSM ROD.

The DNFSB letter of December 5, 1997 also mentioned earthquake faults in the vicinity of TA-3 and the CMR Building; this is discussed under DOE Issue 4. In 1997, LANL geologists initiated a study of the interrelationship of three known geologic faults (Pajarito, Guaje Mountain, and Rendija Canyon faults) in the vicinity of LANL. The preliminary results of that draft study were presented to DOE management [Memorandum, October 28, 1997, Ives, DOE/HQ, to Manager, DOE AL, A.R. No. VII.B-41; Memorandum, Senazi to Trapp, November 13, 1997, A.R. No. VII.B-43; Attachment 1: memorandum, Ives to Manager, October 28, 1997, A.R. No. VII.B-41]. The results to date indicate a possible connection between the three faults, which would increase the likelihood of geologic rupture should a seismic event occur. This could indicate that some buildings in TA-3 might be vulnerable to damage if certain seismic events occurred. DOE requires its sites to review seismic information at about ten year intervals to determine if there is any new information that would result in revising site management actions [DOE Order 420.1, Facility Safety, Sec. 4.4, Natural Phenomena Hazards Mitigation]; LANL has been performing site studies for several years in response to this requirement. Additionally, DOE is conducting an agency-wide review of seismic safety at all of its facilities in response to EO 12941, "Seismic Safety of Existing Federally Owned or Leased Buildings" [59 FR 62545, A.R. No. VII.B-16], and a related DOE implementing guidance memorandum of October 18, 1996 from the Assistant Secretary for Environment, Safety and Health. This report is due to the Federal Emergency Management Administration by December 1, 1998, and has not yet been issued.

The preliminary studies and draft reports indicate the need to consider revising building engineering standards at LANL [Memorandum, Ives to Manager, October 28, 1997, A.R. No. VII.B-41]. The LANL seismic studies do not indicate that the probability of an earthquake event is any more likely than previously thought; the SSM PEIS discussed the known moderate seismic risk at LANL and the possibility of a seismic event as an accident initiator [SSM PEIS, Vol. I, Sec. 4.6.3.5, p. 4-288; Vol. II, Appendix F, Sec. F.2.3.1, p. F-21, F-22; see also SSM PEIS Vol. I, Glossary, definition of "capable fault," p. 9-3]. These studies indicate, however, that DOE, LANL and safety agencies must come to agreement on the amount of seismic protection needed for new and retrofitted buildings at LANL.

Construction of structural modifications such as installing additional seismic bracing would be subject to a NEPA review; this type of facility-specific review if pertaining to implementing pit fabrication decisions would be tiered from programmatic decisions established in the SSM ROD.

While the incidents and studies pointed out in this issue postdate issuance of the SSM PEIS and SSM ROD, actions pertaining solely to budgeting, project management, personnel reorganizations, and developing design standards would not be subject to NEPA. Implementing specific actions pertaining to operational safety or seismic upgrades may be subject to NEPA; however, these would be project-specific NEPA reviews tiered from the SSM analysis, if applicable, and are not germane to programmatic decisions regarding locating the pit fabrication mission.

5. Accidents involving Pu-238. That the PEIS omitted any analysis of accident consequences involving release of Pu-238, where information indicates that two-thirds of the PF-4 space at TA-55 slated for processing Pu-238 would be located in the same building as pit fabrication activities.

The Paine Affidavit, Paragraph 24, refers to alleged new information, Attachment J, that is claimed to shed new light on the accident consequences of processing Pu-238 at TA-55, PF-4. Following completion of the SSM PEIS and assignment of pit fabrication to LANL in the SSM ROD, as part of its site-specific studies to develop an approach to implementing the pit fabrication mission, LANL considered various alternative ways to allocate office and laboratory space at TA-55 and CMR among the various ongoing and newly-assigned missions. The results of that feasibility study were documented in "Alternative for Increasing the Nuclear Materials Processing Space at Los Alamos for Future Missions" [LA-UR-97-1000, April 25, 1997, A.R. No. VII.B-30], which was included as Attachment J to the Paine Affidavit. The feasibility study included, as introductory material in the section cited by Plaintiffs, a summary of the different then-current missions and then-existing space allocations in TA-55. This summary information on mission assignments was not new, and, as explained below, was available to the SSM decisionmaker at the time the SSM ROD was prepared. The feasibility study was included as an attachment to the draft ECDR sent in July 1997 to DOE and DNFSB; the ECDR has not yet been finalized.

LANL carries out Pu-238 operations in TA-55, PF-4, including the manufacture of Pu-238 heat sources for the National Aeronautics and Space Administration (NASA) deep space missions, and has done so for many years under projects such as the Cassini Project ["Environmental Assessment for Radioisotopic Heat Source Fuel Processing and Fabrication," DOE Offices of Special Applications, Assistant Secretary for Space and Defense Energy Systems, DOE/EA-0534, A.R. No. VII.B-3; FONSI 56 FR 34057, July 25, 1991, A.R. No. VII.B-4; "EIS for the Cassini Mission," Solar System Exploration Division, Office of Space Science, NASA, June 1995, A.R. No. VII.B-19; see also Final Supplemental EIS for the Cassini Mission, NASA, June 1997, A.R. No. VII.B-32]. The use of plutonium laboratory floor space at TA-55, PF-4 for Pu-238 work associated with the Cassini mission, including the consequences of release of radiological materials under normal or accident conditions, was specifically assessed in the 1991 EA [DOE/EA-0534, Sec. 4.2.1, p. 4-3; Sec. 6.2.1.2, p. 6-3; Sec. 6.2.2, p. 6-4; FONSI 56 FR 34059]; DOE subsequently implemented this work essentially as described in the EA except that the period of operations for the Cassini project extended until 1996 instead of 1994 as projected in the 1991 EA due to overall project delays. The information regarding collocation of Pu-238 work with other Pu work at TA-55, PF-4, has been in the public venue since mid-1991 and does not represent "new information."

The cumulative radiological impacts of collocating Cassini work and pit processing was mentioned in the SSM PEIS [SSM PEIS, Vol. IV, comment response 11.07]. LANL has always had a limited capacity to manufacture pits [see, for example, SSM PEIS, Vol. IV, response to comment summary 32.12, p. 3-84; and reply to Question 15a from the NRDC questions "Pit Production at Los Alamos: Questions Concerning Environment, Safety and Health Issues," November 1997]. The ongoing mix of plutonium operations at TA-55, which include among other things the current pit fabrication work, Pu-238 operations, and plutonium research and development to support LANL's national security and environmental management missions, was included in the No Action Alternative in the SSM PEIS; the pit production mission is not expected to result in any changes to the PF-4 areas involved in Pu-238 work. DOE continues to conduct these ongoing activities and has in place procedures to assure that new activities will be subject to rigorous safety reviews (which among other things assess the risk of collocating new activities with ongoing operations) before any new activities would be allowed to begin. Therefore, information regarding the collocation of ongoing Pu-238 activities and proposed pit fabrication activities was available to the SSM decisionmaker at the time the SSM ROD was issued. The SSM PEIS provided a programmatic analysis to compare impacts of pit fabrication that would be expected if located at LANL or SRS; it was intended that site-specific impacts of implementing programmatic mission assignments (including the cumulative effects of collocated missions at TA-55) would be analyzed in subsequent tiered NEPA documentation [SSM PEIS, Vol. I, Sec. 1.5, p. 1-8].

The accident analyses of the SSM PEIS were explained in detail in Appendix F, which stated that the issues regarding health risks were twofold: to determine whether accidents at specific facilities would pose unacceptable risks; and which alternative locations would provide an advantage of lesser risk [SSM PEIS, Vol. II, Sec. F.1.1, p. F-1]. The SSM PEIS also acknowledged that specifics regarding measures to reduce risk would be contained in subsequent tiered NEPA reviews, project-specific design reviews, and facility-specific safety analysis reports [SSM PEIS, Sec. F.1.1, p F-2]. The source documents reviewed [SSM PEIS, Vol. II, Table F.1.1-1] made reference to the presence of Pu-238 at TA-55. The SSM PEIS provides a bounding accident analysis and compares the potential health effects from different accident scenarios at LANL and SRS [SSM PEIS, Vol. II, Sec. F.2.3, p. F-16]. [See also SSM PEIS Vol. IV, response to comment 11.08, p. 3-107; and 11.42, p. 3-54.]

The decisionmaker had relevant information available regarding the comparative risk of placing pit fabrication activities at LANL or SRS (including that of collocating pit fabrications activities in the same building as Pu-238 activities), and whether or not the accident risk at any given facility was unacceptable. DOE is obligated to operate TA-55 at LANL in a safe operating configuration (including ongoing activities with Pu-238) regardless of the incremental effect of placing pit fabrication activities at that facility. The decisionmaker knew that Pu-238 activities take place at TA-55, and the decisionmaker weighed whether or not the incremental addition of adding pit fabrication operations to TA-55 posed an unacceptable risk.

This issue was addressed previously in this litigation in the Second Declaration of Albert E. Whiteman. He stated that it has always been acknowledged that Pu-238 operations are carried out in TA-55 PF-4, and are addressed in the TA-55 Safety Analysis Report, A.R. No. I-1124, I-1125 [Second Declaration of Albert E. Whiteman, p. 28]. He stated Pu-238 processes are housed in the north half of PF-4 while pit manufacturing processes are housed in the south half, and discusses safety and accident considerations [Second Declaration, p. 28, 29].

This issue does not present new information that was not available to the SSM decisionmaker. Therefore, no change to the SSM PEIS is warranted.

Analysis of Issues Raised by DOE

1. Pit production strategy.

In September 1997 DOE initiated an evaluation of the potential for fabricating pits in the near-term without displacing other ongoing activities in TA-55. A modified strategy was approved by DOE HQ in December 1997 and transmitted from DOE AL to LANL in January 1998. The strategy in general addressed engineering project management, scheduling, and logistics issues. CMR and Sigma facilities would continue to support pit production. [Memorandum, Whitteman to Cunningham, January 12, 1998, A.R. No. VII.B-50; Attachment 1: memorandum, Ives to Twining, December 16, 1997, A.R. No. VII.B-46; Attachment 2: "Pit Production -- Baseline Program and Project Requirements and Assumptions."]

The three objectives of the modified strategy are:

(a) Decouple the CMIP project for pit fabrication from other projects and focus development of pit production capability at TA-55 without disrupting ongoing mission.
(b) Maintain pit production as a continuous process, and achieve an intermediate capacity of 20 pits per year by FY 2007 without prejudice to the eventual 50 pit per year capacity.
(c) Delay CMIP while performing urgent maintenance and equipment replacement beginning in FY 1999.

The modified strategy in general addresses engineering project management, scheduling, and logistics issues. These types of issues do not result in environmental impacts other than those from implementing the proposed actions, and are generally irrelevant to a NEPA review. The site-specific implementation of CMIP would be subject to project-specific NEPA review. DOE anticipates that the site-specific environmental impacts of implementing the CMIP project will be contained in the LANL SWEIS now under preparation.

The SSM PEIS acknowledged DOE's intent to further refine its plans to implement its programmatic decisions; the SSM PEIS and ROD discussed the two-tiered NEPA strategy and indicated that project-specific decisions on how to implement programmatic decisions would be analyzed in subsequent, tiered, NEPA reviews. DOE is now in the process of refining its plans for implementing the new pit fabrication mission at LANL, and at the same time continuing to carry out its prior pit fabrication missions.

Under the modified strategy, CMR and Sigma facilities would continue to support pit production. The use of these two facilities to support pit production was discussed in the SSM PEIS. As discussed above, the use of Sigma to manufacture nonnuclear pit components was analyzed by DOE in the Nonnuclear Consolidation EA, June 1993, and its related FONSI, September 1993. Implementation of that proposed action began in 1993.

Decoupling the CMIP project from other ongoing construction projects at LANL facilities is a project management (paperwork) activity that would not in itself result in additional environmental impacts. In any case, the CMIP project represents site-specific implementation of programmatic SSM decisions; in accordance with the SSM PEIS and ROD, site-specific implementation would be subject to subsequent, tiered NEPA review.

Maintaining pit production as a continuous process is a project management aspect of implementing this proposal. The comparison of environmental impacts, if any, from differential schedules for implementing pit production would be captured in the project-specific NEPA review for CMIP or its follow-on activities.

Supplement Analysis: Enhancement of Pit Manufacturing at LANL, SSM PEIS

At the same time that they were considering implementation needs for CMIP, DOE and LANL considered the need to expedite certain planned activities at TA-55 so that they would occur prior to CMIP. These are maintenance actions and equipment upgrades that would be needed to conduct LANL's defense mission at TA-55 independent of the pit fabrication mission. Maintenance actions and upgrades to existing equipment at TA-55 would be subject to project-specific NEPA review; the LANL SWEIS is anticipated to consider the cumulative impacts of operating TA-55 under different scenarios, and additional project-specific NEPA review may be needed for any proposed equipment upgrades at the time they are ripe for decision.

The modified strategy for implementing the pit fabrication mission at LANL, as captured in the CMIP project modifications, would be details of site-specific implementation that would not be germane to a programmatic decision to locate this mission. Because it was understood in the SSM PEIS that facilities such as TA-55 needed to be kept in safe operating condition regardless of whether or not LANL received the pit fabrication mission, this issue does not present new information that would bear on the programmatic pit fabrication siting decision. Tiered, project-specific NEPA reviews are planned to cover the CMIP project and improvements to related facilities. Therefore, no change to the SSM PEIS is warranted.

2. CMR project management considerations.

In the SSM PEIS, DOE acknowledged that it could not eliminate any of its weapons manufacturing and component surveillance capabilities [SSM PEIS, Vol. I, Sec. 2.4.2, p. 2-8], and would continue to need all the basic capabilities of its industrial and laboratory base regardless of its decisions to reestablish pit manufacturing capability [SSM PEIS, Vol. I, Sec 2.5, p. 2-10]. The need for analytical chemistry as part of the pit fabrication mission was described in Appendix A [SSM PEIS, Vol. II, Sec. A.3.3, p. A-117, and Figure A.3.3-1, p. A-118]. DOE also acknowledged that its SSM Program would continue to evolve as better information became available and technological advancements occur, and that these future advancements would be subject to future NEPA reviews [SSM PEIS, Vol. I, Sec. 2.5.1, p. 2-10]. One of the ongoing capabilities DOE continues to need in support of its nuclear weapons mission, and independently of any decision to site pit fabrication capabilities, is its analytical chemistry capability at CMR.

Over the past several years, and independent of the need to reestablish pit fabrication, DOE has planned to upgrade the CMR building to extend its useful life to meet ongoing LANL mission requirements. DOE prepared the CMR Upgrades EA [DOE/EA-1101, A.R. No. VII.B-27] and reached a FONSI for the proposed upgrades on February 11, 1997 [A.R. No. VII-B.28]. DOE and LANL immediately began to implement those proposed actions in a sequential manner. LANL was tasked with carrying out certain project management assignments to facilitate design and construction of the upgrades project. In early 1997 it became apparent that costs of the ongoing CMR upgrades project would, unless checked, overrun the FY97 budget. After considering budget, schedules and project management issues, DOE and LANL decided to temporarily suspend construction activities for the CMR upgrades project pending a thorough budget and project management review. [Memorandum, Cunningham to Whiteman, April 24, 1997, A.R. No. VII.B-29; memorandum, Whiteman to Cunningham, May 5, 1997, A.R. No. VII.B-31; letter, Reis to Senator Thurmond, June 19, 1997, A.R. No. VII.B-33; letter, Reis to Senator Domenici, June 19, 1997, A.R. No. VII.B-34. See also Second Declaration of Albert E. Whiteman, June 6, 1997, paragraph 4.g. (p. 8).] Following that review, the upgrades project resumed and upgrade construction activities are underway.

NEPA is a forecasting tool that projects the anticipated environmental impacts that would occur if proposed actions were implemented. The SSM PEIS projected the expected impacts if the pit fabrication mission were to be located at LANL, including use of the CMR Building to support that assignment. The CMR EA analyzed the impacts from constructing the CMR upgrades and the impacts of operating the upgraded CMR Building. The projection and analysis of potential environmental impacts is not dependent on project management considerations such as design and engineering costs, schedules, and skill. These are irrelevant to a NEPA analysis, although they are of interest for other reasons.

This issue raises new information, but not information that is germane to a NEPA review. Therefore, there is no need to supplement the existing NEPA reviews on the CMR upgrades project. The need for the CMR upgrades project is independent of the decision to reestablish pit fabrication at LANL. Therefore, the consideration of the adequacy of the site-specific review of the CMR upgrades project is irrelevant to the programmatic decisions in the SSM PEIS, and does not represent a substantial change to the proposal analyzed in the SSM PEIS. Accordingly, no change to the SSM PEIS is warranted.

3. CMR safety reviews and organizational changes.

On September 2, 1997, in response to safety considerations, LANL temporarily suspended operations within the CMR building pending an in-depth review of all operations and procedures being implemented within the building to support on-going LANL missions. Operations were resumed over time in a phased manner as work control and work authorization procedures were verified for each on-going project within the building. [Memorandum, Gancartz to All CMR Occupants, September 2, 1997, A.R. No. VII.B-38; memorandum, Jackson to Todd, September 5, 1997, A.R. No. VII.B-39.] To further improve operation of the CMR facility within a safe operating envelope for nuclear facilities, LANL Director Browne announced a new integrated management organization for CMR in which the technical, operations, and facility management of CMR would be integrated with that of TA-55. This reorganization became effective in January 1998. [E-mail memorandum, Browne to managers, December 17, 1997, A.R. No. VII.B-47; memorandum, Reis to All CMR and TA-55 Employees, December 19, 1997, A.R. No. VII.B-48; electronic LANL Newsbulletin, "News from John Browne, CMR and TA-55 Integration," January 7, 1998, A.R. No. VII.B-49.]

DOE needs to continue to operate CMR and its other nuclear facilities in a safe, secure manner in order to be able to perform its mission assignments. Operation and management of the CMR Facility is, to some extent, delegated to LANL under its management and operating contract with the DOE. Therefore, it is incumbent upon LANL managers to take actions they deem necessary to ensure that LANL facilities are operated safely and in compliance with operating authorizations.

Management actions such as facility organizational arrangements do not generally, in and of themselves, result in environmental impacts other than those of carrying out the work of the facility. The management actions taken to improve operations at the CMR Building present new information, but not information that is germane to a NEPA review. Consideration of improvements to the management structure at CMR would be a site-specific detail of implementing programmatic mission assignments from the SSM ROD. Therefore, no change to the SSM PEIS is warranted.

4. New earthquake faulting studies at LANL.

As discussed in Plaintiffs' Issue 4 above (consideration of the DNFSB safety concerns), in 1997, LANL geologists initiated a study of the interrelationship of three known geologic faults (Pajarito, Guaje Mountain, and Rendija Canyon faults) in the vicinity of LANL. The preliminary results of that draft study were presented to DOE management [Memorandum, October 28, 1997, Ives, DOE/HQ, to Manager, DOE AL, A.R. No. VII.B-41; Memorandum, Senazi to Trapp, November 13, 1997, A.R. No. VII.B-43; Attachment 1: memorandum, Ives to Manager, October 28, 1997, A.R. No. VII.B-41]. The results to date indicate a possible connection between the three faults, which would increase the likelihood of geologic rupture should a seismic event occur. This could indicate that many buildings in TA-3 would be vulnerable to damage if a seismic event occurred. DOE requires its sites to review seismic information at about ten year intervals to determine if there is any new information that would result in revising site management actions [DOE Order 420.1, Facility Safety, Sec. 4.4, Natural Phenomena Hazards Mitigation]; LANL has been performing site studies for several years in response to this requirement. Additionally, DOE is conducting an agency-wide review of seismic safety at all of its facilities in response to EO 12941, "Seismic Safety of Existing Federally Owned or Leased Buildings" [59 FR 62545, A.R. No. VII.B-16], and a related DOE implementing guidance memorandum of October 18, 1996 from the Assistant Secretary for

Environment, Safety and Health. This report is due to the Federal Emergency Management Administration by December 1, 1998, and has not yet been issued.

The results of the preliminary studies and draft reports suggest that some LANL buildings could be vulnerable to damage in the event of certain seismic events. These studies indicate the need to consider revising building engineering standards at LANL. Promulgating design standards would not be subject to NEPA review, although implementation of any such standards may be. The LANL seismic studies do not indicate that the probability of an earthquake event is any more likely than previously thought; the SSM PEIS discussed the known moderate seismic risk at LANL [SSM PEIS, Vol. I, Sec. 4.6.3.5, p. 4-288; Vol. II, Appendix F, Sec. F.2.3.1, p. F-21, F-22; see also SSM PEIS Vol. I, Glossary, definition of "capable fault," p. 9-3]. These studies indicate, however, that DOE, LANL and safety agencies must come to agreement on the amount of seismic protection needed for new and retrofitted buildings at LANL.

The SSM PEIS considered release of radioactive materials in a seismic accident event and this information was considered by the decisionmaker when deciding to site the pit fabrication mission at LANL. While new seismic studies now underway appear to indicate that there is a need to invest in greater seismic retrofitting to protect building infrastructure, these new studies do not indicate that there would be a greater frequency of seismic events. If new standards are promulgated, buildings at LANL would need to be retrofitted to ensure continuation of safe secure operations to perform ongoing mission requirements regardless of the decision to site the pit fabrication mission at LANL.

The SSM PEIS analyzed the safety and health impacts if a seismic event occurred (regardless of the projected likelihood of this event occurring) and massive structural damage resulted in a release of radioactive materials. The new studies ongoing at LANL do not indicate any preliminary information that would result in a change to the accident analysis presented in the SSM PEIS. Construction activities related to structural modifications would be site-specific actions irrelevant to the programmatic questions considered in the SSM PEIS. Therefore no change to the SSM PEIS is warranted.

CONCLUSIONS

These Issues Do Not Change the SSM PEIS Analysis

The nine issues considered in this Supplement Analysis were either covered in the SSM PEIS and so were available to the decisionmaker; were project-specific issues related to the implementation of SSM decisions at LANL and so would be subject to subsequent tiered NEPA review and decisionmaking; or were preliminary information and so would be subject to future review at such time as they are ripe for decision. Therefore, none of these issues would result in a need to change the SSM PEIS analysis of pit fabrication.

These Issues Do Not Change the SSM ROD

The SSM ROD was based in part on the environmental analysis in the SSM PEIS and in part on other factors. None of the issues raised in the Paine Affidavit, or in the related information considered by DOE, bring forth salient new information bearing on programmatic decisions for siting the reestablished pit fabrication mission of which the decisionmaker was unaware at the time the SSM ROD was issued. Therefore, none of these issues would result in a need to change or amend the programmatic SSM ROD.

RECOMMENDATIONS

Based on the analysis of the issues raised by plaintiff in the Paine Affidavit, DOE does not see any need to supplement the SSM PEIS analysis of reestablishing the former RFP pit fabrication mission at LANL to provide an enhanced pit manufacturing capability. DOE does not believe that any new proposals have emerged which would require preparation of a new EIS at this time. DOE recommends that the SSM PEIS analysis of reestablishing pit fabrication at LANL be left standing and that no additional NEPA reviews, apart from those already planned in the LANL SWEIS or elsewhere, be initiated at this time.

APPENDIX I
REPORT ON THE STATUS AND IMPLICATIONS OF SEISMIC HAZARD STUDIES AT LANL

United States Government **Department of Energy**

Albuquerque Operations Office

memorandum

DATE: JAN 08 1999

REPLY TO: NPD

SUBJECT: Status and Implications of Seismic Hazard Studies at LANL

TO: W. Scott Gibbs, Program Director, MMP, LANL, MS A102

We have reviewed the subject LANL report (dated December 17, 1998), and concur with the conclusions reached regarding the implications of this series of seismic studies. The information summarized in this report and discussed in more detail in the five seismic studies that have been completed, to date, are and will continue to be considered in the execution of mission work at LANL. A specific example of this is the recently approved Interim Technical Safety Requirements for operations at the Chemistry and Metallurgy Research (CMR) Building, which includes reductions in material at risk in that facility and plans for containerization of material in glovebox lines which is not actively being used; these actions are taken to reduce the potential consequences of seismically-initiated accidents in the CMR Building. DOE will continue to examine the mission work at LANL in consideration of seismic and other risks to ensure that such work can be accomplished within acceptable levels of risk.

Should you have any questions on this matter, please contact me (845-6038) or Mr. Corey Cruz (845-6736) of my staff.

Dear Mr. Ives and Mr. Whiteman:

Subject: Transmittal of Los Alamos Report, "Status and Implications of Seismic Hazard Studies at LANL"

Attached for your use is the report "Status and Implications of Seismic Hazard Studies at LANL," December 17, 1998, prepared by Larry Goen, ESA-EA, Los Alamos National Laboratory. The report summarizes the results of five recent seismic studies for various areas at Los Alamos National Laboratory, and makes note of two additional studies that are still in progress. It has been reviewed by staff at both DOE Headquarters and the DOE Albuquerque Operations Office. This final version incorporates comments made by Jeffrey Kimball, seismologist, DOE/HQ DP-45.

The stratigraphic survey for Technical Area (TA) 55 indicates that the area is not susceptible to surface rupture from earthquakes. The stratigraphic survey for TA-3 is in progress and a full report is not expected until March 1999. It appears that surface rupture from earthquakes is not a concern for those facilities at TA-3 that are not nuclear facilities. However, the discovery of a fault under the Chemistry and Metallurgy Research (CMR) Building, which is a nuclear facility, may have implications for decisions concerning the future use of CMR. The seismic studies also address ground motion from earthquakes, and indicate that this hazard is within the parameters assumed in the 1995 probabilistic seismic hazard analysis. The studies conclude that Laboratory structural standards remain valid in regards to ground motion.

Mr. Edwin E. Ives, DOE/HDQS -2- December 22, 1998
Mr. A. Earl Whiteman, DOE/AL
NW/M&M:98-20

I appreciate your interest in this subject. Your office has copies of the completed studies, and we will transmit the remaining studies as soon as they are completed.

Sincerely,

W. Scott Gibbs

Status & Implications of Seismic Hazard Studies at LANL

TABLES

FIGURES

Status & Implications of Seismic Hazard Studies at LANL

1.0 Summary

A number of studies (Table 1) have been initiated in the last two years to address seismic issues at LANL. These studies have focused on the potential for surface rupture at TA-55 and TA-3 and the seismic hazard in general. For surface rupture, studies have centered around the mapping of faults in and around specific technical areas. In addition, a probabilistic surface rupture assessment has been completed for TA-3. For the seismic hazard, studies have focused on the earthquake history on the Pajarito fault.

Table 1 – Seismic Hazard Studies

Task	Status	Ref.
1) Stratigraphic Survey for TA-55	Complete	1
2) FY97 Pajarito Trench Study	Complete	3
3) Probabilistic Surface Rupture Assessment for TA-3	Complete	6
4a) Core Hole Study at SCC/NISC Site	Complete	5
4b) Core Hole Study at CMR Site	Complete	4
5) Stratigraphic Survey for TA-3	In Progress	N/A
6) FY98 Pajarito Trench Study	In Progress	N/A

Surface Rupture

The stratigraphic survey (Ref. 1) for TA-55 is complete and found no evidence for existing faults. Thus the area is not susceptible to surface rupture from earthquakes.

The stratigraphic survey for TA-3 is in progress and a full report is not expected until the end of March 1999. However, it is evident that TA-3 does have faults with vertical displacements in the range of 1-10 feet in 1.2 million year old Bandelier tuff. The heaviest concentration of these faults is in the southeast corner of TA-3. This concentration is believed to be defining the southern end of the Rendija Canyon fault. The faults found include one under the CMR Building (Ref. 4) with a vertical offset of approximately 8 feet.

While surface rupture can cause significant structural damage, surface rupturing earthquakes are low probability events. From the probabilistic assessment of surface rupture (Ref. 6), earthquakes that might result in permanent ground displacements of about four inches are estimated to be 10,000 to 20,000 year events. Four inches was taken as the threshold for a displacement causing severe cracking in a concrete or masonry structure. Earthquakes with would result in permanent ground displacements capable of causing structures to collapse are estimated to be 33,000 to 100,000 year events. The displacement threshold for collapse was taken as about 20 inches.

Based on the probabilistic study (Ref. 6), for non-nuclear structures, surface rupture is not a concern. The performance goal (annual probability of seismic induced damage) for such facilities

Status & Implications of Seismic Hazard Studies at LANL

per DOE guidance is 5 x 10^{-4} (2000 year recurrence interval). Designing to resist the ground motion caused by an earthquake is the primary concern when considering the seismic hazard. While surface rupture not a concern for non-nuclear structures, siting new facilities over known faults should not be done.

For the CMR Building, a nuclear facility, the probability of damaging ground displacement is at or beyond the performance goal for the facility, $1x10^{-4}$ (10,000 year recurrence interval). In its current condition, the probability of damaging ground motion is at least 20 times greater than the probability of damage caused by surface rupture. Therefore, the discovery of the fault under the building does not increase the seismic risk at CMR.

The discovery of a fault under the CMR Building has an impact on decisions concerning upgrades and future uses for the facility. From the seismic perspective, the question which needs to be assessed is whether or not it is prudent to upgrade the structure to resist ground motion loads when the probability of damaging surface rupture is near the performance goal level for the facility. While it is possible to upgrade to resist the forces/displacements caused by permanent ground deformation, the upgrade costs would increase substantially. It should be noted that this site would not be considered adequate for a new nuclear facility.

Ground Motion

In the last two years, a number of trenches have been excavated to study the earthquake history on the Pajarito fault. The purpose of the studies has been to determine when the most recent ground rupturing event occurred on the fault, to get a better understanding of recurrence intervals for earthquakes (slip rate), and to help determine if the three main faults in the Los Alamos area are connected.

For the seven trenches excavated in June 1998, data analysis is in progress and preliminary results are not available. For the seven trenches excavated in July 1997, the results (Ref. 3) show that the most recent event occurred 1500-2000 years ago with no other events in the last 10,000 years. The slip rates determined from this study indicate that they are within the parameters assumed in a 1995 probabilistic seismic hazard analysis. The 1995 study is the basis for the LANL design basis ground motion.

The significance of this information is that there is no direct evidence that the three local faults (Pajarito, Rendija Canyon and Guaje Mountain faults) are connected and the assumptions made in the probabilistic seismic hazard assessment completed in 1995 are still valid. Therefore, the design basis ground motion defined in the LANL structural standards is still valid.

Status & Implications of Seismic Hazard Studies at LANL

2.0 Introduction

In FY 1997, the first two tasks shown in Table 1 were undertaken to better understand the seismic hazard at the Los Alamos National Laboratory (LANL) site. One study was to investigate the possibility of the Rendija Canyon fault extending through Technical Area 55 (TA-55). The other was to investigate seismic history on the Pajarito fault, the main contributor to the seismic hazard for return periods of greater than 1,000 years. From preliminary results of these two studies, questions were raised concerning the possible connection of the Pajarito, Rendija Canyon and Guaje Mountain faults, shown in Figure 1, and surface rupture at TA-3. Both of the studies were finalized in FY98.

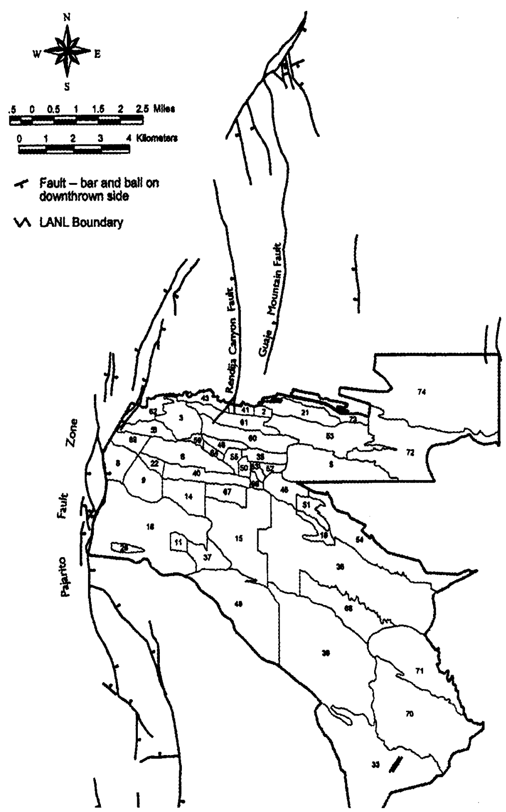

Figure 1 – Major Surface Faults at LANL

At TA-55, the study (Ref. 1) found that the Rendija Canyon fault does not project through TA-55 and that the site is free of any observable faulting. The study did find evidence for faulting further to the west, in the vicinity of TA-3. Data collection for the mapping of the faulting in the TA-3 area, the sixth task shown in Table 1, began in October, 1997 and continued through September 1998. Although the data have only been partially analyzed, it is evident that faulting is present in TA-3.

On the Pajarito fault, trench studies were conducted to try to estimate the last event on the fault, to try to estimate recurrence intervals on events, and to estimate slip rates. All of these factors were assumed in the seismic hazard evaluation (Ref. 2) completed in 1995 and physical data is needed to confirm that the assumptions made were conservative. The investigation (Ref. 3) initiated in FY97 has resulted in finding the most recent event on the Pajarito approximately 1500 - 2000 years ago and that slip rates were consistent with those assumed in Reference 2. In addition, a similar study, the sixth task in Table 1, began in FY98. For the FY98 study, the fieldwork is complete and data analysis is in progress.

In this report, the results of these studies plus those either completed or in progress are discussed as well as what the implications are for new and existing construction in TA-3. Findings for individual studies are first presented followed by a summary of DOE seismic requirements. Finally, the impacts on the understanding of the seismic hazard on facilities at LANL, in particular those in TA-3 such as CMR are presented.

Status & Implications of Seismic Hazard Studies at LANL

3.0 Findings to Date

The emphasis for work over the last two fiscal years falls in two categories: the potential for surface rupture at TA-55 and TA-3, and, investigation of the seismic history on the Pajarito fault.

3.1 Surface Rupture Investigations

Work in this area can be divided into three areas, fault mapping at TA-55 (1st task in Table 1), fault mapping at TA-3 (4th and 5th tasks in Table 1), and probabilistic surface rupture assessment of TA-3 (3rd task in Table 1).

3.1.1 Fault Mapping and Surface Rupture Investigation at TA-55

In Reference 1, results are presented of high-precision geologic mapping in the vicinity of TA-55 that has been done to identify parts of the southern portion of the Rendija Canyon fault, or any other faults, with the potential for seismic surface rupture. To assess the potential for surface rupture at TA-55, an area of approximately 3 square miles that includes the Los Alamos County Landfill and Twomile, Mortandad, and Sandia Canyons has been mapped in detail.

This mapping indicates that there is no faulting in the near surface directly below TA-55, and that the closest fault is about 1500 feet west of the Plutonium Facility. Faulting is more abundant on the western edge of the map area, west of TA-48, near TA-3, in uppermost Mortandad Canyon, upper Sandia Canyon, and at the County Landfill. With the exception of the County Landfill, measured vertical offsets ranged from 1 to 8 feet. At the County Landfill, faulting exposed has a distributed zone of faulting over 1000 feet wide with a net down to the west vertical displacement of 15 feet. Individual faults within this zone have vertical offsets ranging from 1 to greater than 15 feet. The area mapped is shown in Figure 2 (Ref. 1).

3.1.2 Fault Mapping and Surface Rupture Investigation at TA-3

The surface rupture investigation at TA-3 includes locating and mapping of existing faults using two different methods. One of methods used is high precision location of stratigraphic contacts using total station surveying techniques in the canyons to the north and south of TA-3. The other method is the drilling of core holes to locate stratigraphic contacts at specific sites, namely the CMR site (Ref. 4) and the proposed site for the Strategic Computing Center (SCC) and Nonproliferation and International Security Center (NISC) projects (Ref. 5), within TA-3.

High Precision Mapping at TA-3:

High precision mapping at TA-3, similar to that accomplished in the TA-55 area, is an in-progress study. Data collection for this study was completed in September, 1998. Data analysis and report writing is ongoing. The final report is expected to be completed in March, 1999.

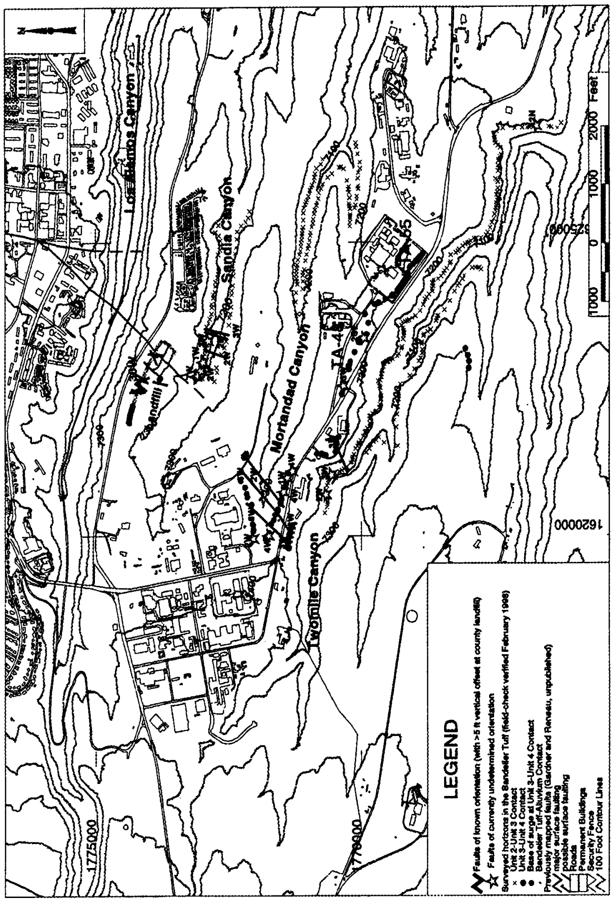

Figure 2 – Map of Faulting in TA-55 Area (Ref. 1)
Numbers and leeters adjacent ot faults indicate the amount of displacement (in feet) and sense of displacement (e.g., 4W = 4 feet of displacement down to the west).

The areas surveyed in the data collection portion of this study are indicated in Figure 3. Along with the survey locations, Figure 3 also depicts the location of linear features found in the examination of air photos dating to the 1940's. The linear features could indicate the location of faults, but could also indicate other linear features such as fences trails and roads. These linear features are being used as guides in the data analysis currently underway. As the data analysis progresses, it is expected that some of the air photo lineaments will be designated faults while others will be removed from the map.

Status & Implications of Seismic Hazard Studies at LANL

Although data analysis is in progress, preliminary findings indicate faulting is present in the TA-3 area. The majority of the faults is in the southeastern area of TA-3. These faults have vertical offsets in the range of 1 to 10 feet.

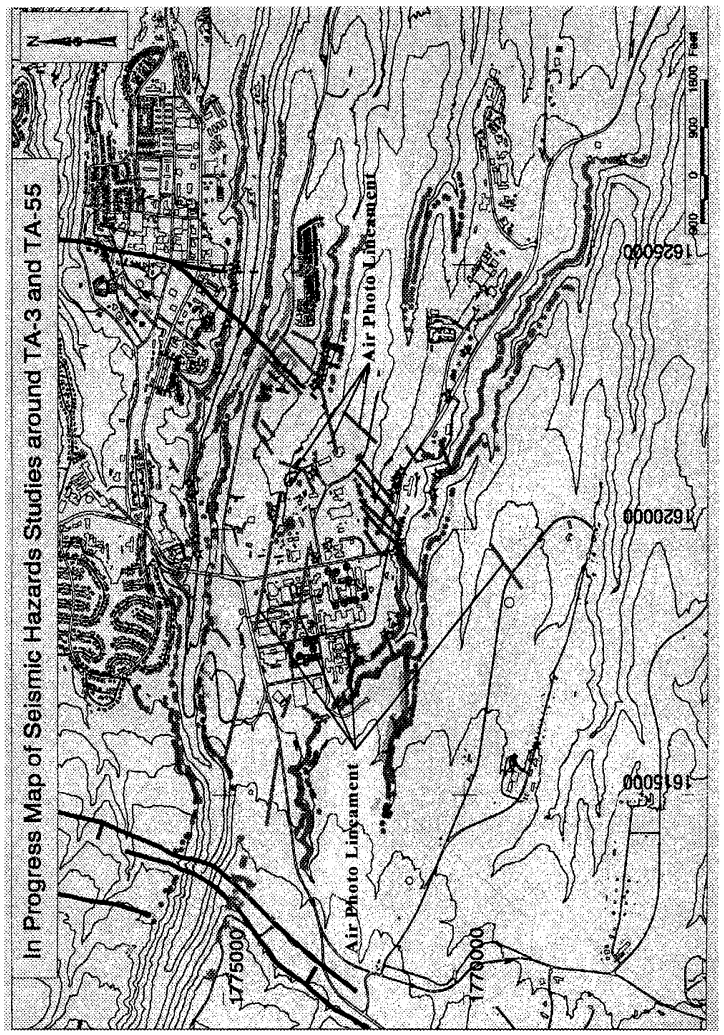

Figure 3 – In Progress Map of Fault Location in TA-3
Unless indicated as "Air Photo Lineament" (purple lines), lines indicate faults of known orientation. Stars represent faults of unknown orientation. Dots indicate surveyed points of stratigraphic contacts.

Status & Implications of Seismic Hazard Studies at LANL

CMR Core Hole Investigation:

At the site of the existing Chemistry and Metallurgical Research (CMR) Building, nine closely spaced, shallow holes were drilled. The purpose of the holes was to obtain the cores and to establish the elevation at which contacts between particular layers of the Bandelier Tuff are located. These elevations were then used to develop a contour map at a particular contact. Abrupt changes in the contours would indicate the presence of faulting. The goal of the investigation was to identify faults that may have the potential for earthquake-induced surface ruptures at the site.

Analysis (Ref. 4) of the data obtained indicates that a fault is present at the CMR Building. Its location and inferred orientation are shown in Figure 4. The fault is contained within the core obtained from the CMR-6 and can be inferred to occur between the CMR-2 and CMR-3 locations. This orientation is consistent with one of the air photo lineaments shown in Figure 3. The total displacement of Unit 3 in the CMR-6 core is approximately 8 feet.

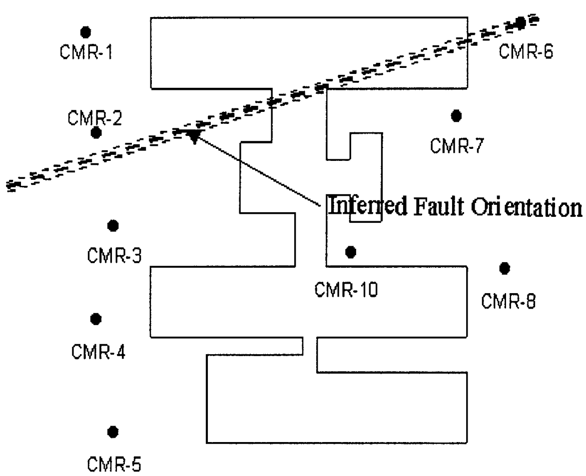

Figure 4 – Plan View of CMR Building With Inferred Location of Fault

Based on this investigation, it can be concluded that the CMR Building site has, in the past, been impacted by fault rupture. However, as discussed later in this report, the probability of an earthquake causing significant surface displacement at this site in the future is small.

SCC/NISC Core Hole Investigation:

At the site proposed for the new Strategic Computing Center (SCC) and the new Nonproliferation and International Security Center (NISC) projects, ten closely spaced, shallow holes were drilled. The purpose of the holes is the same as the holes drilled at the CMR Building.

Status & Implications of Seismic Hazard Studies at LANL

From analysis (Ref. 5) of the data gathered, there is no evidence for faults under the building sites. Because no significant or cumulative faulting events have disturbed the site in the last 1.22 million years, the age of the Bandelier Tuff, it is unlikely that surface rupture will occur at the site in future large earthquakes.

3.1.3 Probabilistic Surface Rupture Analysis

A probabilistic seismic hazard analysis for potential surface fault displacement at TA-3 has been performed and is described and summarized in Reference 6. The objective of the analysis was to estimate the potential surface rupture hazard posed by the Pajarito fault system, in particular, a possible splay of the Rendija Canyon fault that may transect TA-3. The principal products of this study are probabilistic surface rupture hazard curves for the CMR and SCC/NISC sites. The study focused on these two sites at TA-3 and provides bounding case assessments of the surface rupture potential at each site.

Three different cases were considered in the hazard analysis: (1) distributed faulting only; (2) principal faulting at the CMR site; and, (3) principal faulting at the SCC/NISC site. Principal faulting is faulting occurring along the main plane(s) of crustal weakness responsible for the release of seismic energy during an earthquake. Distributed faulting is defined as rupture that occurs on other faults, shears, or fractures in the vicinity of the principal rupture in response to the principal displacement. The three cases correspond to three different possible scenarios for the southern end of the Rendija Canyon fault. For Case 1, three different hypothetical conditions were assumed: (a) a distributed fault with 9m of cumulative displacement in the Bandelier Tuff, (b) a distributed fault with 1m of cumulative displacement, and (c) a fracture with no observable displacement in the tuff. A total of 15m of cumulative displacement is assumed in cases 2 and 3.

The results, summarized in Table 2, show that for annual frequencies of 10^{-4} or larger, surface rupture is minimal or nonexistent. The hazard curves developed for the two sites are shown in Figures 5 and 6. Hazard curves that investigate the sensitivity of the three main faults being connected or not are shown in Figure 7.

Table 2 – Probabilistic Surface Rupture Results

Annual Frequency	Case 1a	Case 1b	Case 1c	Case 2&3
10^{-4}	<1 mm	<1 mm	<1 mm	2 cm
10^{-5}	50 cm	20 cm	10 cm	70cm

3.2 Paleoseismic Investigations

Recent paleoseismic investigations have focussed on the Pajarito Fault. Two separate but related studies were initiated in Fiscal Year 1997 and Fiscal Year 1998. Locations of the studies are shown in Figure 8. Fieldwork for the paleoseismic studies is completed in a fairly short time frame but the analysis of samples required to develop date constraints is a time consuming process. Thus, work initiated in one fiscal year typically carries over to the following fiscal year to obtain dating information.

3.2.1 FY97 Paleoseismic Investigation on the Pajarito Fault

In July 1997, seven trenches were excavated across strands of the Pajarito fault zone to characterize the most recent faulting event (MRE), and to refine characterization of previous faulting events. The strategy for capturing the MRE was to excavate a series of seven trenches along an east-west transect across the fault zone south of Los Alamos Canyon, where parallel faults span a zone nearly 2 km wide. Two of the seven trenches were located on the main 50 m high scarp of the Pajarito fault, with the remainder on smaller east- and west-facing scarps. This study is presented in Reference 3.

Status & Implications of Seismic Hazard Studies at LANL

The best paleoseismic records were preserved on scarps that faced west, or upslope. Each of these trenches displayed evidence of mid- to late-Holocene MRE. The MRE appears to fall in a relatively narrow age range between about 1300 to 2300 years ago with a likely age of about 1500 years.

The MRE dated at about 1500 years does not appear to be contemporaneous with the MRE on the Guaje Mountain fault, dated at 4000-6000 years or the MRE on the Rendija Canyon fault, dated at either 8 or 23 thousand years. The trenches on the Pajarito do not show evidence for either a second (or third) earthquake at either 4000-6000 years or 8000 years. Thus, it appears that the MREs on each of the three faults in the Pajarito fault system are separate earthquakes.

3.2.2 FY98 Paleoseismic Investigation on the Pajarito Fault

In June, 1998, seven additional trenches were excavated across the Pajarito fault zone further south than the FY97 study. Again, the purpose of the excavations was to characterize the most recent faulting event (MRE), and to refine characterization of previous faulting events. While the fieldwork is complete, analysis of the data obtained is ongoing. The final report is to be complete in March, 1999.

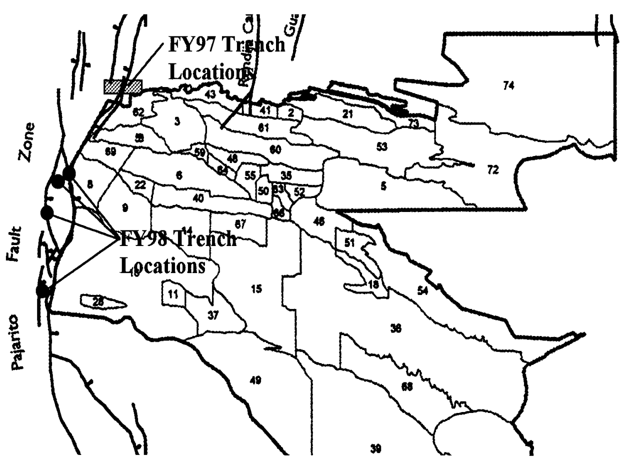

Figure 8 – Locations of Paleoseismic Studies

Status & Implications of Seismic Hazard Studies at LANL

4.0 DOE Requirements

The DOE, through orders and standards, provides guidance for facility siting and design with respect to earthquakes. The guidance is probabilistically based.

The Implementation Guide to DOE Order 420.1 "Natural Phenomena Hazards for DOE Nuclear Facilities and Non-Nuclear Facilities" (Ref. 7) requires that structures systems and components be designed and constructed to withstand the effects of natural phenomena hazards (NPH) using a graded approach. The target safety levels for structures systems and components (SSCs) subject to NPH are given in the guide in terms of performance goals. These performance goals are defined as the acceptable annual probability of failure. The performance goals are shown in Table 3 and are a function of performance categorization. Performance categorization is determined in accordance with DOE STD 1021 (Ref. 8). The guide also states that siting of structures over active geologic faults should be avoided.

Table 3 - Performance Goals and Categories for SSCs

Performance Category	Description of Performance Required	Seismic Performance Goal
PC0	No consideration.	N/A
PC1	Prevent major structural damage or collapse which would endanger personnel (life-safety).	$1x10^{-3}$
PC2	Maintain operation of essential facilities allowing relatively minor structural damage.	$5x10^{-4}$
PC3	Confinement of hazardous materials.	$1x10^{-4}$
PC4	Confinement of hazardous materials	$1x10^{-5}$

DOE STD 1020 (Ref. 9) specifies seismic loading in probabilistic terms. The annual exceedance probability for the ground motion associated with the various performance categories is shown in Table 4. The peak ground accelerations for LANL are based on the information in Reference 2.

Table 4
Peak Ground Accelerations at LANL

Performance Category	Annual Probability of Exceedance (Return Period)	Horizontal Peak Ground Acceleration (g)	Vertical Peak Ground Acceleration (g)
PC1	$2x10^{-3}$ (500 yr.)	0.15	0.11
PC2	$1x10^{-3}$ (1,000 yr.)	0.22	0.19
PC3	$5x10^{-4}$ (2,000 yr)	0.31	0.27
PC4	$1x10^{-4}$ (10,000 yr)	0.57	0.58

For seismic design, the standard recommends using deterministic design rules that are familiar to design engineers and which have a controlled level of conservatism. This level of conservatism combined with the specification of probabilistic seismic loading leads to performance goal achievement.

Status & Implications of Seismic Hazard Studies at LANL

DOE STD 1022 (Ref. 10) provides guidance for NPH Characterization Criteria including the necessity for establishing the potential for surface rupture and points to EPA guidance for offsetting hazardous waste facilities from active faults. Active faults are characterized "by the presence of surface or near surface deformation of geologic deposits of a recurring nature within the last approximately 500,000 years or at least one in the last approximately 50,000 years."

DOE STD 1023 (Ref. 11) provides criteria for NPH assessment. In this document, some guidance is provided for ground failure (surface rupture). If surface rupture may occur near a facility, a probabilistic evaluation may be necessary. If the annual probability of ground failure is greater than the necessary performance goal either the site should be avoided, mitigation measures taken, or an evaluation performed of the effects of fault offset.

15 December 17, 1998

Status & Implications of Seismic Hazard Studies at LANL

5.0 Implications of Findings

This section discusses the implication of the findings on projects at TA-3 and for the Laboratory in general. These studies have implications for LANL in two areas: (1) surface rupture potential at TA-3 with respect to both non-nuclear facilities and the CMR Building, and (2) design ground motion for all facilities.

5.1 Surface Rupture at TA-3

The studies to date indicate that there are faults in some locations at TA-3 including under the CMR Building. These faults will be addressed in a manner consistent with DOE guidance. For new facilities, building sites will be selected such that "active" faults are avoided. For existing facilities that are located over faults, assume they meet "active" criteria and a probabilistic approach will be followed.

Non-Nuclear Facilities (PC 1 and PC 2):

For the SCC and NISC projects, a site specific study (Ref. 5) was performed to determine if faulting was present at the proposed site. The results of this study indicate the site is clear of faulting and is therefore acceptable for new construction.

For existing facilities, hazard curves developed in the probabilistic surface rupture study (Ref. 6) for TA-3 are used. At the performance goals for PC 1 and PC 2, $1x10^{-3}$ and $5x10^{-4}$, respectively, the estimated displacement for any of the cases as shown in Figures 4 and 5 and summarized in Table 2 is less than 1 millimeter. This is true even for the case where all faults are assumed to be connected. This small amount of displacement has a negligible effect on structures. Therefore, for existing PC 1 and PC 2 facilities, surface rupture is not a credible hazard and the only aspect of the seismic hazard at TA-3 that should be considered is ground motion.

The CMR Building (PC 3)

As previously indicated, it has been determined that there is an existing fault under the CMR. The vertical offset in this fault is approximately 8 feet. The identification, location and orientation of the fault under the CMR shown in Figure 4 is based on air photo interpretation, high precision mapping of faults in canyons to the south of TA-3, and examination of cores taken from the nine holes drilled around the CMR Building. The air photos indicate a linear feature running through the CMR site from the northeast corner of the facility and through the site to the west-southwest. The high precision mapping effort located a fault with about 5 feet of vertical offset in Twomile Canyon to the southwest which coincides with the southwest end of the air photo feature running through the CMR site. The examination of the cores showed that the core taken at the northeast corner (CMR-6) of the facility cut through a fault with a total vertical offset of about 8 feet and that it is likely that the same fault lies between cores CMR-2 and CMR-3. This information also coincides with the air photo feature. The location and orientation of the fault shown in Figure 4 are consistent with the information known to date.

Status & Implications of Seismic Hazard Studies at LANL

If this site were to be considered for a new nuclear facility, it would not be used and an alternate site, clear of faulting concerns, would be chosen. However, since this is an existing facility, the impact on the safe operation of the facility must be assessed. For this assessment a probabilistic approach is used.

The CMR Building is a PC 3 facility that contains special nuclear materials. The performance goal for design basis earthquakes is $1x10^{-4}$. The vertical offset of the fault under the facility lies between the existing conditions evaluated in cases 1a (9m offset) and 1b (1m offset) in Reference 6. As shown in Table 2, the probable offset for these cases at the performance goal is less than 1 mm. This small amount of displacement has a negligible effect on structures and it could be concluded that the discovery of this fault is not a credible hazard for the design basis event.

However, if the worse case assumption is made that this is a principal fault and that all three faults are connected, the estimated offset from Figure 6 for the PC 3 performance goal is approximately 10 centimeters (4 inches). A displacement of this magnitude can cause significant cracking in a concrete shear wall structure such as those used in the construction of the CMR Building. This cracking could result in a loss of confinement.

It can be shown (Ref. 12) that the annual probability of seismic induced failure, based on ground motion associated with an earthquake, is about $2x10^{-3}$ for most areas of the CMR Building. The exceptions to this is the vault that has an annual probability of seismic induced failure, again, based on ground motion, of about $7x10^{-5}$, and the floor wells which have yet a lower probability of failure. The significance of this information is that ground motion could cause a loss of confinement for most areas of the CMR Building at frequency that is at least 20 times greater than surface rupture.

In the safety analysis for the CMR Building, the consequences of the seismic accident are assessed assuming that the CMR building, with the exception of the vault and floor wells, collapses at the frequency indicated above. With the vault and floor wells located such that they would not be directly effected by a surface displacement, the assumptions used in the safety analysis for the seismic accident are still valid even with new knowledge of a fault beneath the facility.

Based on current available information, the fault under the CMR site is a subsidiary fault. As a result, any movement on the fault is likely to be small and would be a result of a large (Magnitude 6 to 7) earthquake on the Rendija Canyon or the Pajarito fault. Such earthquakes are low probability events. In Figure 9 the estimated annual frequency of damage caused by ground motion is compared to the annual frequency of damage caused by surface rupture. This figure illustrates that damaging surface rupture is far less likely to occur than damaging ground motion.

Status & Implications of Seismic Hazard Studies at LANL

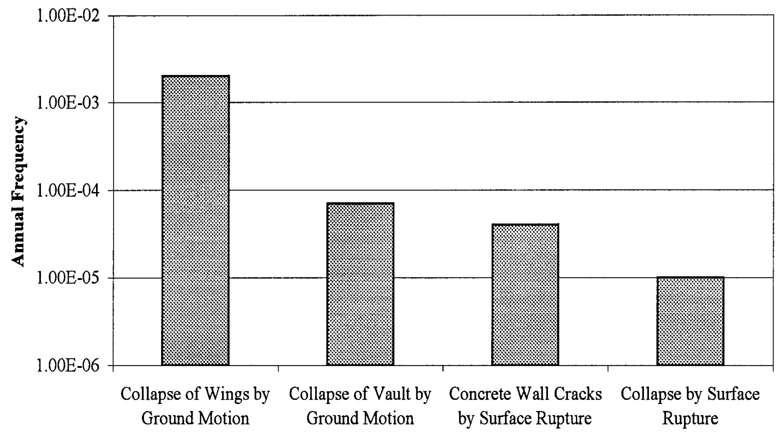

Figure 9 – Frequency of Seismic Induced Damage at CMR Building

5.2 Design Ground Motion

Of the current seismic hazard studies, only the paleoseismic investigations could influence the design ground motion at LANL. At this time only the information from the FY97 study can be assessed for its impact.

The design ground motion at LANL is based on the results of the probabilistic seismic hazard analysis (PSHA) presented in Reference 2. According to this reference, the net slip rate of the Pajarito fault is the most important input parameter in the PSHA. For this fault the PSHA assumed the slip rates shown in Table 5. One of the objectives of the paleoseismic investigations is to get a more accurate assessment of the slip rate on the Pajarito fault.

Table 5 – Net Slip Rates for Pajarito Fault Used In PSHA

Net Slip Rate (mm/yr)	Probability[1]	Percentile[2]
0.01	0.1	5th
0.05	0.2	20th
0.09	0.4	50th
0.20	0.2	80th
0.95	0.1	95th

[1]Probability used in PSHA Logic Tree
[2]Cumulative percentile

Based on the results of the FY97 paleoseismic investigation (Ref. 3) on the Pajarito fault, the net slip rate is 0.06-0.21 mm/yr. The lower of the two values is less than the median slip rate value of 0.09 mm/yr assumed in the PSHA. The higher of the two values is approximately equal to 80th

Status & Implications of Seismic Hazard Studies at LANL

percentile motion assumed in PSHA. Therefore, the slip rates calculated in the 1997 study are already covered in the PSHA documented in Reference 2.

Questions concerning the dependency of the three major faults are based on the physical location and style of deformation of the three faults. Their relative proximity to one another and style of deformation could lead to the conclusion that they must be connected at depth below the earth's surface. However, based on the paleoseismic studies to date, there is no evidence that supports this conclusion. The MRE on the Pajarito fault, dated at 1500-2000 years, is not coincident with either the MRE on the Guaje Mountain fault, dated at 4000-6000 years or the MRE on the Rendija Canyon fault, dated at either 8 or 23 thousand years. The trenches on the Pajarito do not show evidence for either a second (or third) earthquake at either 4000-6000 years or 8000 years.
